# TABLE OF CONTENTS

<b>ACKNOWLEDGEMENTS.....</b>	<b>5</b>
<b>LIST OF TABLES .....</b>	<b>6</b>
<b>LIST OF FIGURES .....</b>	<b>7</b>
<b>ABSTRACT .....</b>	<b>10</b>
<b>1 INTRODUCTION .....</b>	<b>11</b>
<b>2 MATERIAL MODELS - THEORIES.....</b>	<b>15</b>
2.1 Introduction.....	15
2.2 Material models and theories .....	15
2.3 Time-independent constitutive theories for cyclic plasticity .....	17
2.4 Constitutive theories based on microscopic and/or crystallographic phenomenological descriptions .....	20
2.5 Constitutive rate-dependent theories.....	22
2.6 Constitutive modeling of cyclic plasticity and creep using an internal time concept.....	23
2.7 Creep-plasticity interaction and unified models.....	24
2.8 Similarities between models .....	25
2.9 Chaboche EVP model .....	26
2.9.1 Constitutive Laws.....	27
<b>3 USER-DEFINED MATERIAL MODELS - METHODS OF IMPLEMENTATION IN FEM SOFTWARE.....</b>	<b>32</b>
3.1 Introduction.....	32
3.2 Methods for user-defined model implementation .....	32
3.2.1 Object oriented software, modules and classes .....	33
3.2.2 Z-Mat .....	34
3.2.2.1 Z-Mat Material Behaviours .....	37
3.2.2.2 Material Files.....	38
3.3 Z-Mat Chaboche model implementation.....	39
<b>4 MATERIAL CHARACTERIZATION .....</b>	<b>41</b>
4.1 Introduction.....	41
4.2 Material Characterization – Theory .....	42
4.2.1 Experimental tests .....	42
4.2.2 Tensile Test.....	42
4.2.3 Fatigue Test.....	46
4.2.4 Creep Test .....	49
4.2.5 Constitutive laws .....	51
4.2.6 Chaboche model coefficients .....	53
4.3 Material Characterization – Numerical methods.....	54
4.3.1 Methodology of characterization.....	54
4.3.2 Optimization method.....	56
4.3.3 Identification tools .....	57
4.3.3.1 Simulation tool .....	57
4.3.3.2 Optimization tool.....	59
4.3.4 Validation of characterization methodology .....	62
4.4 Material characterization – Analysis of experimental data .....	63
4.4.1 Material features.....	64
4.4.2 Experimental tests .....	64
4.4.2.1 Tensile tests .....	64
4.4.2.2 LCF tests.....	66
4.4.2.3 LCF - step tests .....	70
4.4.2.4 Creep tests.....	71
4.4.3 Elasto-visco-plastic behaviour model of René 80 .....	74
4.4.4 Validation of René 80 material model.....	75

4.4.4.1	FEM simulation of LCF tests.....	75
4.4.4.2	FEM simulation of creep tests .....	79
4.5	Limits of the automatic procedure of characterization.....	81
4.5.1	High number of coefficients and problems of solution convergence .....	82
4.5.2	Quality and variety of experimental tests.....	83
4.5.3	Non uniqueness of parameters set .....	93
4.5.4	Sensitivity of the model to the single parameters (E, R0) .....	95
4.5.5	Differences between a model with one kinematic hardening mechanism and a model with two kinematic hardening mechanisms.....	97
4.6	Design of experiments .....	99
4.6.1	Check by phenomenological aspect .....	101
<b>5</b>	<b>APPLICATION OF ELASTO-VISCO-PLASTIC MATERIAL MODELS TO CASES OF INDUSTRIAL INTEREST. ....</b>	<b>104</b>
5.1	Introduction.....	104
5.2	Procedure of elasto-visco-plastic analysis.....	104
5.2.1	Test case .....	106
5.2.2	Linear-elastic analysis .....	109
5.2.3	Elasto-plastic analysis .....	110
5.2.4	Elasto-visco-plastic analysis .....	115

## Acknowledgements

I take the opportunity to acknowledge and thank all the people that helped me throughout this process.

I want to acknowledge my family for the love and the support they gave me, if it was not for my mother, my father, my brother and my sister, I would not have finished or either started such activities.

I would like to express my sincere gratitude to my tutors: Professor Sergio De Rosa and Professor Francesco Franco for their guidance. Without their support this work would never have been.

I would like also to thank Ansaldo Energia, which allowed me to use, within all the allowed company policies, materials and resources in order to bring this work at the end. A special thank goes to Ing. Mauro Macciò, Ing. Franco Rosatelli, Ing. Andrea Bessone.

I would like to thank Professor Leonardo Lecce who allows me to collaborate with my first sponsor for this activity AVIO Aerospace Propulsion - Research and Development Department.

I would like to express my appreciation to my ex-colleague and friend, Engineer Salvatore Costagliola who started with me working on the main subject of this study. I also would like to thank people from *Ecole de Mines* – Paris and ANSYS Inc. corporation for providing me valuable help in using respectively the software Z-Mat and the user subroutine USERMAT.

## **Abstract**

The main goal of this work is the analysis of the procedure for material characterization aimed at elasto-visco-plastic models and their implementation in FEM codes. This will be done in order to perform stress analysis of structural components under repeated cyclical loads and high temperatures

The overall development involves theoretical, numerical and experimental methodologies.

The study of state of the art of material models, available in FEM codes, has allowed the evaluation of the limits of stress analysis on components subjected to repeated cyclical loads and high temperature. The initial study has also highlighted the necessity to implement complex material models. Traditionally this lack has been faced through the use of factors of safety, which are developed and refined on the basis of the experience and historical backgrounds. For systems where efficient design is of the utmost importance (for example the minimum weight design of an aircraft structure), it is possible that the traditional factors of safety may be overly conservative, so that optimal efficiency cannot be achieved. The implementation of complex material models allows simulating the real material behaviour and taking into account the non-linear interaction between creep and fatigue for structural analysis and life prediction. The results are more dependable and allow reducing the traditional factors of safety, consequently lead to a significant improvement in the designing of structural components.

The process of material characterization has been developed through the following phases: designing the necessary experimental data base, choosing the constitutive laws, describing the iterative procedure for determining the coefficients of material model and the procedure of model validation, performed by comparisons between experimental data and simulated ones.

It has been described how a poor experimental data base influences the material characterization process and the limits of an automatic procedure. Guidelines have been provided for designing experimental tests able to identify the optimized model parameters. In this way, it will be possible to determine material models with wide range of validity and to allow reducing time and costs of a characterization process.

A methodology of structural analysis has been developed through the comparison with procedures of tested validity, in way to allow a correct and safe implementation of elasto-visco-plastic material models. An elasto-visco-plastic analysis on a combustion chamber of aeronautical engine has been performed and component life determined, taking into account the interaction between fatigue and creep.

# 1 Introduction

The principle that has inspired this work is to investigate how the mechanical properties of materials are affected by complex loading histories and how this behaviour in turn affects the performance of engineering components.

The approach is global. A theoretical formulation is combined with discriminating experiments and numerical methodologies to define and calculate the factors which affect the life and performance of engineering components subjected to severe loading conditions. An approach of this type has the ability to be constantly improved. Incremental improvements in constitutive laws, for example, may be introduced as are efforts which help to bridge the physical processes within the material and the macroscopic behaviour observed in experiment.

The request to obtain refined simulations of a real behaviour, in structural analysis, is one of the most important goals that actually researchers are attempting to reach. Actually, the automated calculation procedures that structural analyst uses through Finite Element Modelling (FEM), allows reaching a very high level of refinement, if one refers to the prediction of the structural behaviour of a component/machine under a very complex load system. In this field, the capability to be able to reproduce material behaviours is one of the most interesting points because the ability to manage the material matrix in FEM software is the necessary starting point to have a satisfying result.

The study of state of the art of material models, available in FEM codes, has allowed the evaluation of the limits of stress analysis on components subjected to repeated cyclical loads and high temperature. The initial study has also highlighted the necessity to implement complex material models. Traditionally this lack has been faced through the use of factors of safety, which are developed and refined on the basis of experience and historical evidence. For systems where efficient design is of the utmost importance (for example the minimum weight design of an aircraft structure) it is possible that the traditional factors of safety may be overly conservative, so that optimal efficiency cannot be achieved. Furthermore, historical factors of safety are unlikely to be appropriate for new design concepts or new complex metal super-alloys. These materials, for instance, have very different behaviours if we consider that depending mainly on the type of load and the temperature. They can present hardening, softening, cyclic stabilization, stress relaxation, creep, etc.

The main goal of this work is to provide a procedure for material characterization aimed at elasto-visco-plastic models and their implementation in FEM codes. This will be done in order to perform stress analysis of structural components under repeated cyclical loads and high temperatures. The implementation of complex material models allows simulating the real material behaviour and taking into account the non-linear interaction between creep and fatigue for structural analysis and life prediction. The results are more dependable and allow reducing the traditional factors of safety, consequently lead to a significant improvement in the designing of structural components.

The coupled plasticity and creep behaviour of the materials subjected to complex loading histories at elevated temperature has been intensively attractive in recent years due to the following motivations from which the new problems of load-bearing systems will mainly arise: to increase performance, to extend life to avoid failure (Leckie, 1985). For these purposes, materials will be required to work under more adverse operating conditions, so that, on one hand, high-performance materials are

required and, on the other hand, a reliable estimation for operational life and failure analysis has to be performed. As its premise, the research on more realistic constitutive models becomes more and more significant.

Early in the 50s Besseling (1958) proposed a theory of plasticity and creep. From then on, remarkable progress has been made in the modelling of the constitutive behaviour of materials at elevated temperature. With more and more understanding of the coupled plasticity and creep behaviour, people no longer tend to simply separate the inelastic deformation into time-independent plastic and time-dependent creep parts, but treat it as a unified irreversible one caused by thermodynamic activation. Based on this concept various unified constitutive descriptions were proposed. Robinson (1978) proposed a constitutive relation by extending the potential theory of plasticity to include plasticity-creep interaction; Chaboche (1983), Krempl (1987), Phillips and Wu (1973) developed the descriptions for coupled plasticity-creep on the basis on nonlinear theory of viscoplasticity; Hart (1976), Miller (1976), Ponter and Leckie (1976) built up their models with various kind of microscopically based phenomenological constitutive theories. Freed and Walker (1993) proposed a viscoplastic theory, which reduces to creep and plasticity when time-dependent and time-independent conditions are considered, respectively. Based on the endochronic theory of viscoplasticity (Valanis, 1980), Watanabe and Atluri (1986) suggested a definition of intrinsic time, which leads to the evolution of the back stress that takes into account the thermal recovery as used in the famous Bailey-Orowan's relationship, and proved that Chaboche's model of viscoplasticity can be considered as one of its special cases. Wu and Chin (1995) investigated transient creep with a unified approach based on the endochronic constitutive evaluation. Murakami and Ohno (1982) proposed an elaborate creep model based on the notion of creep-hardening surface related to the dislocation motion under reversed stress history, which well described the creep of 304 stainless steel subjected to biaxial stress history. Meanwhile, systematically experimental studies on the coupled creep and plasticity of materials subjected to multiaxial complex loading histories have also been conducted and provided a series of significant results (Murakami and Ohno, 1986; Inoue et al. 1985).

On the other hand, the constitutive models without using a yield surface were also developed and investigated (Valanis, 1980; Valanis and Fan 1983; Fan and Peng, 1991; Murakami and Read, 1987), in which inelasticity is considered to be a gradually developing process which may be initially extremely small, but develops with increasing loading. These kinds of models are also significant due to Drucker (1991). The result of an extensive analysis of the literature is certified by the papers reported in the literature review used for the present work: they will be recalled in the overall development of the work.

Herein, the elasto-visco-plastic Chaboche model is investigated; it is based on the implementation of energy potentials that, combined each other, describe the mechanism of plastic dissipation and deformation evolution. (Lemaitre and Chaboche, 1990)

In order to obtain a visco-plastic formulation that can be considered valid within a wide strain rate range, using a unified complete model, the elasto-visco-plastic Chaboche model introduces a multipotential plasticity/visco-plasticity formulation. For this reason, plastic deformation is divided into two different terms: visco-plastic deformation for high strain rates and visco-plastic deformation for slow strain rates. Both strain potentials have visco-plastic features, their strain functions depend directly from time. In Chaboche model, kinematic hardening rule is non linear and is expressed through Armstrong-Frederick non-linear law (1966). This nonlinear kinematic hardening model, compared to Prager model (1949) defines the kinematic variable evolution in the time, in way to take into account the effects of deformation history. Besides, in order to take into account both variation of

size elastic domain (isotropic model) and its translation (kinematic non-linear model), it has been chosen the combined Chaboche model (Delprete et al., 2007). It allows describing the hardening evolution for metallic material under repeated cyclic loads.

The work starts from analysing the state of art of material models. Chapter 2 describes the main time-independent constitutive theories for cyclic plasticity developed to define elasto-plastic material behaviour under cyclic loadings. Subsequently, main time-dependent constitutive theories for visco-plasticity are analysed. Many different concepts are proposed in literature for representing thermo-mechanical behaviour of materials: constitutive theories based on microscopic and/or crystallographic phenomenological descriptions, visco-plastic theories based on intrinsic time function, unified models based on the interaction between creep and plasticity, until to the description of elasto-visco-plastic Chaboche theory that is at the base of the material model chosen in this work.

Chapter 3 provides a short account of the theories and methods for modelling materials behaviour and their numerical implementation. A modelling method based on object oriented programming has been chosen and modular software which allows creating objects and classes to associate each one has been utilized. Through advanced program design techniques, it is possible to built material behaviour routines using “material model building bricks” (such as yield criterion, isotropic or kinematic hardening evolution, visco-plastic flow) to create a modular, flexible model based on fundamentals. The routines containing the constitutive equations can be interfaced with FEM software and its supporting utilities.

Chapter 4 analyses the process of material characterization. Since the vastness of the dealt topics, it has been divided in five sections: theory, numerical methods, analysis of experimental data, limits of automatic procedure of characterization, design of experiments. In the first section it will be provided a theoretical description of characterization tests and of Chaboche elasto-visco-plastic model chosen for the present application. In particular, implemented constitutive laws and meaning of model parameters will be described. Numerical methods section shows the procedure developed for determining coefficients of material model: an iterative process in which the starting parameters, given by tentative, are “fitted” to the real curves through a process of simulation and optimization. The optimal model parameters are chosen so as to minimize the least-square distance between experimental data and simulated curves generated by simulation tool. The validation of process is obtained implementing material model in FEM software for performing simulations of characterization tests. By the comparison between model response and experimental data, the model predictive capability is evaluated. In the section on the analysis of experimental data, the procedure will be applied for characterizing a Nickel base super-alloy extensively used in high temperature components of jet engines and gas turbines for power generation. A detailed analysis of available experimental tests and a selection of them will be performed for determining parameters set of model. It will be then highlighted the limits of automatic characterization procedure in the dedicated section, and it will be shown that the main difficulties associated with the use of complex constitutive equations to predict the behaviour of high temperature components are the number of parameters to be handled and the quality of experiments performed. The last section will provide guidelines for designing experimental tests able to identify optimized parameters set of material model. It will be shown that a sufficient number of repetitions for each test, as well as a sufficient variety of experimental data should be provided in order to obtain a model with a general character and a wide field of validity. Besides, it will be provided indications about which types of test to be led for

characterization process and for validating the predictive behaviour of the model. Finally, it will be described how to verify the goodness of the model through phenomenological aspects derived experimentally.

Chapter 5 describes a procedure for FEM structural analysis developed through the comparison with procedures of tested validity, in way to allow a correct and safe implementation of elasto-visco-plastic material models. In particular, starting from an elasto-visco-plastic material model, already characterized and validated, it will be tested its effectiveness through comparison analysis with known models in linear-elastic and elasto-plastic fields. It will be shown that elasto-visco-plastic analysis allow simulating the real material behaviour under repeated cyclic loads and high temperatures, as well as evaluating components life in a more accurate way, taking into account nonlinear interaction between fatigue and creep. In fact, it will be analysed a procedure for calculating structure life by the implementation of known creep and fatigue damage models and the application of Chaboche theory of damage nonlinear accumulation. The stress analysis procedure will be applied to a case of industrial interest. An elasto-visco-plastic analysis will be performed on a combustion chamber of aeronautical engine and structure life will be evaluated. Finally, it will be evaluated the response of material model characterized in this work, performing an elasto-visco-plastic analysis on a portion of turbine blade. Starting from these results, it will be possible to plan a new campaign of experimental tests for a complete material characterization. The introduction of such complex models will allow an improvement of turbine blades designing. As a matter of fact, the capability of reproducing the real material behaviour and predicting the component life in a more dependable way, allow reducing the traditional factors of safety that are overly conservative and preventing from achieving the optimal efficiency in structural designing process.

The concluding remarks of this work are in Chapter 6, which analyses the material characterization process as result of the user choices and discusses the obtained and achievable results.

It has to be highlighted that the present work involves part of the frontier continuum mechanics. The ambitious objective of the contemporary research programm is to face such complex topics on modelling material behaviour taking into account the nonlinear interaction between creep and fatigue. The most important and difficult aspect of modeling material behaviour at elevated temperature is to obtain the required material functions for viscoplasticity and associated material parameters.

The complexity of this subject stems from not only the variety in mathematical forms for the material functions, but also from the fact that given the material functions, there is no unique set of material parameters for any given load path.

Therefore, numerous iterations and difficult compromises are required before a final set of material parameters (for the assumed material functions) can be obtained.

The data and some experimental results herein discussed were originated from database made gratefully available by Avio Propulsione Aerospaziale and Ansaldo Energia.

## 2 Material Models - Theories

### 2.1 Introduction

The main requirement of large deformation problems such as structural components design, life prediction, high-speed machining, impact, and various primarily metal forming, is to develop constitutive relations which are widely applicable and capable of accounting for complex paths of deformation. Achieving such desirable goals for material like metals and steel alloys involves a comprehensive study of their microstructures and experimental observations under different loading conditions.

In general, metal structures display a strong rate and temperature dependence when deformed non-uniformly into the inelastic range. This effect has important implications for an increasing number of applications in structural and engineering mechanics.

The mechanical behavior of these applications cannot be characterized by classical (rate independent) continuum theories: they do not incorporate *material length scales*.

It is therefore necessary to develop a rate-dependent (visco-plasticity) theory for closing the gap between the classical theories and the micro-structure simulations.

In this chapter, an overview is provided concerning the constitutive theories *time-independent* for cyclic plasticity and *time dependent* for visco-plasticity.

Then, it will be introduced the main constitutive elasto-visco-plastic theories (EVP) until to arrive at the description of EVP Chaboche constitutive laws that are at the base of the material model chosen in the present work.

In order to focus the present discussion on the theories of viscoplasticity, the basic constitutive theories are reported in Appendix A.

### 2.2 Material models and theories

The development of power systems with greater thermodynamic efficiency makes the need for accurate analytical representations of inelastic deformation a necessity. More complex material models have been developed to support this emerging need. These mathematical models must be capable of accurately predicting:

- *short-term plastic strain,*
- *long-term creep strain, and*
- *their interaction.*

Multiaxial, cyclic, and non-isothermal conditions are becoming the norm, not the exception, and the capability to implement these features became an issue in the three past decades. This is the reason why, such a formidable task has received considerable attention, resulting in an emerging field of continuum mechanics called elasto-visco-plasticity.

The theoretical development of visco-plasticity has its origin with the works of Stowell (1957), Prager (1961), and Perzyna (1963), whose theories did not contain evolving internal state variables.

The field blossomed in the 1970's when rapid advances in computing technology enabled accurate solutions to be obtained readily. Internal state variable theories began to appear in the models of Geary and Onat (1974), Bodner and Partom (1975), Hart (1976) and Miller (1976), Ponter and Lechie (1976), Chaboche (1977), Krieg et al. (1978), and Robinson (1978).

Theoretical refinements have continued to occur throughout the 1980's in the models of Stouffer and Bodner (1979), Valanis (1980), Walker (1981), Schmidt and Miller (1981), Chaboche and Rousselier (1983), Estrin and Mecking (1984), Krempl et al. (1986), Lone and Miller (1986), and Anand and Brown (1987).

Reviews on various aspects of visco-plasticity have been written by Perzyna (1966), Walker (1981), Chan et al. (1984), Lemaitre and Chaboche (1985), and Sweeney and Holbrook (1985).

The inelastic material behaviour of metals is often involved in technical processes like metal forming. The material properties of metals are well investigated (see e.g. Benallal et al., 1989; Bruhns et al., 1992; Chaboche and Lemaitre, 1990; Haupt and Lion, 1995; Khan and Jackson, 1999; Krempl, 1979; Krempl and Khan, 2003; Lion, 1994) and the origin of the visco-plastic behaviour is well understood.

Basically, the distortion of the metallic lattice as well as the production and motion of dislocations leads to a static hysteresis and non-linear rate dependence. It is worthy to be mentioned that the rate-dependent behaviour of metals is already observable at moderate strain-rates (cf. Haupt and Lion, 1995; Krempl, 1979; Lion, 1994).

In order to represent the inelastic behaviour of metals a lot of constitutive theories were developed: see e.g. Bertram (2003), Bucher et al. (2004), Bruhns et al. (1992), Green and Naghdi (1965), Haupt and Kamlah (1995), Miehe and Stein (1992), Lehmann (1983), Rajagopal and Srinivasa (1998a), Scheidler and Wright (2001), Simo and Miehe (1992), Tsakmakis (1996), and Tsakmakis (2004) for a common overview see the textbooks Haupt (2002) and Lubliner (1990). Furthermore, the visco-plastic behaviour of metals is discussed in Chaboche (1977), Haupt and Lion (1995), Krempl (1987), Lion (2000), and Perzyna (1963).

It is known that because of the different crystallographic orientation of the grains in polycrystalline metal materials, micro stresses in such materials differ considerably (also because of the anisotropy of the coefficient of elasticity) from the average stresses both by the value and by the direction of the deviator vector. For this reason, the micro plastic deformations differ considerably in terms of value from the average deformation and this induces residual stresses usually referred to as residual stresses of type II, which cause the Bauschinger effect (Lemaitre and Chaboche, 1990) and plastic hysteresis. It is evident that the time-independent micro plastic deformations and micro-creep deformations may take place both when deforming with stresses higher and lower than the elastic limit and may produce the relaxation of internal stresses of type II.

The processes of micro- and macro-creep were linked and it was shown that the character of the process of micro stress relaxation was similar to that of macro stress relaxation. Which deformations, micro plastic or micro creep, are larger in magnitude in conditions of stresses under the elastic limit, including cyclic stresses, is a question that can only be answered on the basis of experimental results. It is known, as proved by the analysis of data on the micro deformations of different materials under single loading, that at low temperatures the micro plastic deformations are considerably larger.

However, in the case of cyclic deformation the process of development of micro plastic deformations in many materials is slowed as the number of cycles increases, whereas the rate of accumulation of micro-creep deformations under cyclic alternating loading increases with the number of cycles.

At high temperatures, the micro-creep deformations are considerably larger than the micro plastic deformations.

### **2.3 Time-independent constitutive theories for cyclic plasticity**

In the engineering practice there are numerous applications in which cyclic loads are applied on mechanical components. In metallic materials, by analyzing shape and placement of hysteresis cycles, it is possible to observe the main typical non-linear phenomena of plastic deformation evolution of material, under cyclic loads: Bauschinger's effects, ratchetting, cyclic hardening or softening and mean stress relaxation (Voyiadjis and Park, 1997; Habraken et al., 1997).

Analytical description and numerical simulation of these phenomena are an issue to determine a safe valuation of fatigue life of materials and components (Mroz and Seweryn, 1997; Voyiadjis et al., 1998) when loading conditions involve non-linear behaviour of material.

In literature vary constitutive models have been developed that allow to define elasto-plastic material behaviour under external loads (Lemaitre and Chaboche, 2000; Hubel, 1996; Guillemer et al., 1999). The concepts of classical time-independent plasticity are very old. For monotonic loading isotropic or linear-kinematic rules are generally considered good enough to predict stresses and strains in structures.

During the last years, the increased knowledge of the actual behaviour of materials (low-cycle-fatigue), the emergence of several industrial applications involving the prediction of stresses and strains under cyclic loadings, led to the development and the use of different constitutive equations in cyclic plasticity. At high temperature, maybe eventually at room temperature, the problem becomes more complex due to the effects of time (creep, viscoplasticity, recovery, aging, etc.).

In the first part of the chapter, the attention is focused on the time-independent structure of constitutive equations (Chaboche, 1986). In the second part, it will be dealt the viscoplasticity and recovery (Chaboche, 1983a,b; 1984).

When considering cyclic plasticity, that is the development of constitutive equations describing the behaviour of materials under cyclic plastic strains, different kinds of formulations can be adopted. Two classes emerge from the literature, based on one of the following thermodynamical concepts:

- The actual state of the material depends on the present values and the past history of observable variables only (total strain, temperature, etc.) giving rise to hereditary theories.
- The actual state of the material depends only on the present values of observable variables and a set of internal-state variables.

The first concept was used for example by Valanis (1971-1980) in the development of the endochronic theory, by Krempl (1975) in viscoplasticity, by Guelin et al. (1977) in the hereditary theory with discrete memory events.

The second approach is studied under many different ways in order to generalize the classical isotropic and linear kinematic theories:

- using multilayer concepts (Besseling, 1958 and Meijers 1980),
- by means of multiyield surfaces (Mroz 1967),
- with two surfaces only (Dafalias et al., 1976 and Krieg, 1975),
- in terms of differential equations (Armstrong and Frederick, 1966; Malinin and Khadjinsky, 1972).

All the above theories consider the partitioning of strain into elastic and plastic parts which, in the small strain hypothesis, writes as

$$\varepsilon = \varepsilon_e + \varepsilon_p \quad (2.1)$$

Another common feature is the use of a yield surface concept, in the stress space:

$$f = f(\sigma, \text{hardening}) \leq 0 \quad (2.2)$$

$f < 0$  indicates the elastic domain. Plastic flow takes place if  $f = 0$ .

Figure 2.1 illustrates the concept together with the classical normality hypothesis for the plastic strain rate:

Figure 2.1 - Schematic of the elastic domain, normality hypothesis, load-unload criterion

$$d\varepsilon_p = d\lambda \frac{\partial f}{\partial \sigma} \quad (2.3)$$

In the following, only the associated flow rules are considered, in which the yield surface and the loading surface (or plastic potential surface) coincide. A third common hypothesis is relative to the loading-unloading criterion. The subspace  $f > 0$  is excluded.

At constant temperature, the plastic flow only occurs if the loading index,  $\Gamma$ , is positive:

$$\Gamma = \frac{\partial f}{\partial \sigma} \otimes d\sigma \quad (2.4)$$

where the symbol  $\otimes$  indicates the contracted tensorial product. The opposite case implies elastic unloading (see Figure 2.1, b).

All the models considered are a generalization in some way of the linear kinematic rule introduced by Prager (1949), where the yield surface is described by

$$f = \phi(\sigma - c\varepsilon_p) - k = 0 \quad (2.5)$$

Here the translation of the yield surface is denoted by the kinematic stress tensor (or back stress or rest stress):

$$X = c\varepsilon_p; \quad dX = c \, d\varepsilon_p \quad (2.6)$$

and the plastic multiplier  $d\lambda$  is determined through the consistency condition of time independent plasticity:  $f = df = 0$ .

It is simple to find at constant temperature, by using equations (2.3) and (2.4):

$$df = \frac{\partial f}{\partial \sigma} \otimes d\sigma - \frac{\partial f}{\partial \sigma} \otimes dX = \frac{\partial f}{\partial \sigma} \otimes d\sigma - c \, d\lambda \frac{\partial f}{\partial \sigma} \otimes \frac{\partial f}{\partial \sigma} = 0 \quad (2.7)$$

Taking account for the yield condition and the load-unload criterion leads to

$$d\lambda = H(f) \frac{\left\langle \frac{\partial f}{\partial \sigma} \otimes d\sigma \right\rangle}{c \left( \frac{\partial f}{\partial \sigma} \right) \otimes \frac{\partial f}{\partial \sigma}} \quad (2.8)$$

Where:

- $H$  is the Heaviside function,  $H(u) = 0$  if  $u < 0$ ,  $H(u) = 1$  if  $u > 0$ , and
- the brackets are defined by  $\langle u \rangle = u H(u)$ .

Then the Equation (2.3) can be rewritten as follows:

$$d\varepsilon_p = \frac{1}{c} H(f) \langle n \otimes d\sigma \rangle n \quad (2.9)$$

where  $n$  is the unit outward normal to the yield surface

$$n = \frac{\frac{\partial f}{\partial \sigma}}{\left[ \frac{\partial f}{\partial \sigma} \otimes \frac{\partial f}{\partial \sigma} \right]^{1/2}} \quad (2.10)$$

The hardening module is the constant  $c$ ,

$$c = \frac{d\sigma \otimes d\varepsilon_p}{d\varepsilon_p \otimes d\varepsilon_p} \quad (2.11)$$

It has just described kinematic hardening, which represents rapid changes in the dislocation structure. During each half-cycle (in tension-compression for example) dislocations are remobilized when unloading and reverse loading take place. Then kinematic hardening gives a description of monotonic rapid evolutions during each branch in a cyclic loading.

Independently of the kinematic effect, accumulation of dislocations can be represented by the accumulated plastic strain. The corresponding strength modification can be introduced in the modelling through a change in the width of the elastic domain: This change is given by the isotropic internal stress in equation:

$$f = J(\sigma - X) - R - k = 0 \quad (2.12)$$

where the kinematic and isotropic variables are  $X$  and  $R$ , respectively, which define position and size of the yield surface;  $k$  is the initial size of the surface, with  $R(0) = 0$ .

The isotropic internal stress is directly related to the increase in the dislocation density, but may also depend on the dislocation configuration, e.g. creation of dislocation cells, size and fineness of the cells, etc.

## 2.4 Constitutive theories based on microscopic and/or crystallographic phenomenological descriptions

Many different concepts are proposed in the literature for representing the thermo-mechanical behaviour of material bodies: e.g. Jou et al. (1996), Maugin and Muschik (1994), Meixner and Reik (1959), Muller and Ruggeri (1998), Truesdell and Noll (1965), and Ziegler (1977).

The development of the constitutive equations follows a thermo-mechanical framework, which was established by Coleman and Gurtin (1967), Coleman and Noll (1963), and Truesdell and Noll (1965). In this theory, the second law of thermodynamics is represented by the local form of the Clausius–Duhem inequality and implies a constraint, which must be satisfied by the constitutive relations for every admissible thermodynamic process (cf. the discussions in Jou et al. (1996) and Maugin and Muschik (1994)). In contrast to this concept, Germain et al. (1983) introduces a pseudopotential of dissipation and Green and Naghdi (1978) as well as Ziegler (1977) suggest a constitutive relation for the rate of dissipation (cf. the remarks in Maugin and Muschik (1994)). In these frameworks, the

evolution equations of internal variables are often determined by using the postulate of maximum dissipation (cf. Deseri and Mares, 2000; Miehe, 1998; Rajagopal and Srinivasa, 1998b), which can be traced back in its thermo-mechanical formulation to Ziegler (1963) and Ziegler (1977). In plasticity theory, a related concept was formulated by von Mises (1928) and Hill (1950).

In addition to the modelling of the mechanical behaviour, the representation of the thermo-mechanical coupling phenomena is of special interest (Bodner and Lindenfeld, 1995; Chaboche, 1993b; Hakansson et al., 2005; Haupt et al., 1997; Helm, 1998; Jansohn, 1997; Kamlah and Haupt, 1998; Mollica et al., 2001; Tsakmakis, 1998): it is well known that metals show thermoelastic coupling phenomena. Moreover, a part of the work required to produce plastic deformations is stored as internal energy in the microstructure of the material. Since the basic results of Taylor and Quinney (1934), this phenomenon has been investigated in detail: cf. Bever et al. (1973), Chrysochoos et al. (1989), Helm (1998), Oliferuk et al. (1985), and Rosakis et al. (2000). In the first studies (cf. Taylor and Quinney, 1934), a small amount of approximately 11% of the introduced cold work is stored in the microstructure. In contrast to this, subsequent studies (e.g. Bever et al., 1973; Chrysochoos et al., 1989; Helm, 1998; Oliferuk et al., 1985) led to the result that the stored energy depends on the deformation history and that more than 11%, up to approximately 70%, of the cold work is stored in the microstructure of the material.

A theory of viscoplasticity with adequate capabilities for modelling polycrystalline metals was developed by Freed (1988). He developed a theory derived from physical and thermodynamical considerations. The flow equation is of classical form. The dynamic recovery approach is shown to be superior to the hardening function approach, for incorporating nonlinear strain hardening into the material response through the evolutionary equation for back stress. A novel approach for introducing isotropic strain hardening into the theory is presented, which results in a useful simplification. In particular, the limiting stress for the kinematic saturation of state (not the drag stress) is the chosen scalar-valued state variable. The resulting simplification is that there is no coupling between the two state variables in the flow equation, and there is no coupling between dynamic and thermal recovery terms in each evolutionary equation. This derived theory of viscoplasticity has the structure of a two-surface plasticity theory when the response is plasticlike, and the structure of a Bailey-Orowan creep theory when the response is creeplike. Its development was most strongly influenced by the viscoplastic theories of Ponter and Leckie (1976) and Chaboche (1977).

Ponter and Leckie's theory is based on a Bailey-Orowan theory of creep (Bailey (1926) and Orowan (1947)), Chaboche's theory is based on a two-surface theory of plasticity (Dafalias and Popov, 1975; Krieg, 1975). Others have also formulated viscoplastic theories based on those of Ponter and Leckie (e.g., Robinson, 1978) and Chaboche (e.g., Walker (1981)).

Thermodynamics with internal variables offers a good framework to introduce constitutive equations. It offers both a guideline and some constraints for the choice of thermodynamically consistent evolution equations. A special form uses the notion of a standard generalized material, where the complete thermo-elastic-inelastic behaviour is defined from the knowledge of two potentials; the thermodynamic potential to describe the present state and the dissipative potential for the irreversible evolutions.

Introducing mechanical constitutive models into a thermodynamic framework allows the partition of the plastic work into the energy stored by the material and the one dissipated away as heat. The constitutive equations are derived from the first and second laws of thermodynamics, the expression of

Helmholtz free energy, the additive decomposition of the total strain rate into elastic and visco-plastic, the Clausius-Duhem inequality, the maximum dissipation principle, generalized normality, and the thermo-mechanical heat equation. The visco-plastic yield criterion is of a *von Mises* type, but it needs to be modified to account for high-strain rates and temperature dependency. This is done by replacing the yield strength, the hardening function, and the viscous stress by the physically based flow stress model. The irreversible thermodynamic process can be characterized by a time incremental approach allowing for the equilibrium thermodynamic characterization. The irreversible thermodynamic is compensated for by introducing internal state variables such that they are implicitly non-equilibrated by a set of fictitious thermodynamic conjugate forces.

## 2.5 Constitutive rate-dependent theories

The inelastic response of materials is perhaps inevitably rate-dependent. When material rate-dependence is accounted for, there is no loss for ellipticity in quasi-static problems and wave speed remains real, as long as stress levels remain small compared to elastic stiffness. Even though the phenomenology of localization can be the same for both rate-dependent and rate-independent material behaviour, pathological mesh dependence does not occur in numerical solutions for rate-dependent solids because boundary value problems remain well posed. The rate independent solid does emerge as the appropriate limit.

One approach to remedying this situation is to explicitly introduce a length scale into the material characterization by using a nonlocal constitutive relation. Material rate-dependence, no matter how small, leads to well posed boundary value problems with unique solutions. This can be viewed in terms of material rate-dependence implicitly introducing a length scale into the boundary value problem formulation. Of course, in any particular circumstance, the question remains as to whether or not this is the relevant length scale.

Since modern structures exhibit a strong rate-dependency especially at elevated temperatures, the constitutive relations, which have been developed to describe the behaviour of different types of metals, must be able to reproduce these facts. Processes related with high velocities therefore must be described by a rate-dependent visco-plasticity whereas the same constitutive relations for vanishing velocities must turn over to a rate-independent plasticity. Prior to establishing constitutive relations that can fulfil these conditions, a proper physical interpretation of the phenomena observed during inelastic deformation is needed.

This means that the different mechanisms that can explain the dissipation implied by internal changes of the material are to be analyzed. It is known from appropriate microscopic investigations that in a temperature, strain rate spectrum in general different regions can be observed reflecting different mechanisms of inelastic deformation. Following some of them:

- Athermal mechanisms characterized by a yield stress (e.g. face centred cubic metals) or hardening stress (e.g., body centred cubic metals) relatively insensitive to the strain-rate;
- Thermally activated dislocation motion. Characterized by a more markedly, temperature and rate-sensitivity of the yield and hardening stresses.

Rice (1971) developed theoretical foundations of constitutive relations at finite strain for a class of solids exhibiting inelasticity as a consequence of specific structural rearrangements, on the microscale of constituent elements of material. Metals deforming plastically through dislocation motion are of this class and form the primary application of the theory. The development is in terms of a general internal-variable thermodynamic formalism for description of the microstructural rearrangements, and it is shown how metal plasticity may be so characterized. The principal result is in the normality structure, which is shown to arise in macroscopic constitutive laws, when each of the local microstructural rearrangements proceeds at a rate governed by its associated thermodynamic force. This provides a theoretical framework for time-dependent inelastic behavior in terms of a “flow potential”, and reduces to statements on normality of strain increments to yield surfaces in the time-independent case. Conventional characterizations of the stress-state dependence of metallic slip are noted to be in accord with this concept of associated forces governing rates, so that the resulting normality structure may be considered directly applicable to metal plasticity.

A rate-dependent constitutive theory was developed by Freed (1988): the Omega-form theory of visco-plasticity, which is the normality structure of a potential function Omega. The advantage of this approach is that the choice of two scalar-valued functions of state, completely defines a mathematical structure for viscoplasticity. The disadvantage is that the theory may be too restrictive. This approach results in a theory where inelastic strain-rate strongly influences the evolution of state, as is the case in creep of metals. The ensuing discussion does not address physical justification for the existence of the Omega function; rather, it concentrates on the mathematical consequences of such function. From this theory a flow equation and an evolutionary equation for back stress were derived. The structure of this evolutionary equation was altered to introduce an evanescent strain-memory effect through the addition of dynamic recovery term.

## **2.6 Constitutive modeling of cyclic plasticity and creep using an internal time concept**

Typical constitutive relations for creep reported and used in literature include the modified strain hardening rule developed by researchers at the Oak Ridge National Lab (Pugh et al., 1972, Corum et al., 1974), dislocation models (Lagneborg, 1971, Gittus, 1976) based on metal physics, nonlinear viscoelasticity theory (Besseling, 1958); and the kinematic hardening model (Malinin and Khadjinsky, 1972) using an analogy to plasticity. However, efforts in material-constitutive-model development reveal a trend toward unifying creep and plasticity. Some experimental results (Corum et al., 1974, Jaske et al., 1975) were reported concerning the interaction between creep and plasticity. Further details on the creep-plasticity interaction and unified models will be provided at the following paragraph. Here, it is presented only a brief introduction, in which it is shown how these unifying theories may be roughly divided into three categories of:

- Potential theories
- Microphenomenological theories
- Nonlinear viscoplastic theories

Most studies employ these theories either individually or in combination. In the first category, one may cite the theories using time-dependent parameters (Kratochvil and Dillon, 1970), the concept of kinematic hardening (Kujawski and Mroz, 1980), micromechanical considerations (Ponter and Leckie, 1976) and a combination of viscoplastic theory (Chaboche, 1977). The phenomenological theories

(Bodner and Partom, 1975; Hart, 1976, Hart et al., 1976; Miller, 1976a, 1976b; Krieg et al., 1978; Robinson, 1978; Stouffer and Bodner, 1979) employ certain internal variables to reflect the micromechanics of deformation, such as involving dislocations. Most of these theories assume that the plastic strains are also time-dependent, as are creep strains, and that the creep surface will translate and expand in the stress-space in a manner similar to that of isotropic and kinematic hardening used in classical plasticity theory. The nonlinear viscoplasticity theories have the variations, in which: the coefficients of the linear viscoelastic theory (Cernocky and Kremple, 1980) are expressed as a function of stresses and strains, the inelastic strains are divided into viscous and viscoelastic components (Findley and Lay, 1978), and the internal time is measured by the (total) strain history (Valanis, 1971a, 1971b, 1980; Bazant and Bhat, 1976; Bazant, 1978, Wu and Yip, 1980, 1981; Valanis and Fan, 1983). Of course, the fundamental aspects of inelastic deformation are also studied (Rice, 1970, 1975; Hill and Rice, 1972) based on micromechanical considerations.

The intrinsic time theory, labelled “the endochronic theory” was presented by Valanis, (1971a, 1971b). This theory held out the prospect of explaining the experimental phenomena of cross-hardening, cyclic hardening, and initial strain problems, the situations that classical plasticity theory could not cope with. Bazant and Bhat (1976) also showed that the endochronic theory is effective in dealing with problems of inelasticity and failure in concrete, and that Maxwell chain model can describe the creep behaviour.

Valanis (1980) later presented a slightly modified intrinsic time model, wherein the internal time is related to the inelastic strain. Valanis and Fan (1983) presented an incremental or differential form of the integral relation of stress and strain (Valanis, 1980) for plasticity. This differential relation (Valanis and Fan, 1983) is of a fundamentally different form as compared to that of the classical plasticity theory and does not employ the notion of a yield surface nor the attendant concepts of “elastic” and “plastic” processes. Based on such a differential relation, Valanis and Fan (1983) developed an “initial strain” type iterative finite element approach. In this approach, the determination of stress history (or the stress rate) from a given strain history (or the strain rate) is also highly iterative in nature.

While using the concept of an intrinsic time, which depends on plastic strains, and the integral relations of stress and strain (Valanis, 1980), Watanabe and Atluri (1986) rederive a differential stress-strain relation, such that:

- The concept of a yield surface is retained
- The definitions of “elastic” and “plastic” processes are analogous to those in classical plasticity theories
- It can be implemented in a computationally simple and efficient manner, via a “target-stiffness” finite element method, and a “generalized-midpoint-radial-return” algorithm for determining the stress history (or the stress rate) for a given strain history (or strain rate).

They also developed a simple theory for creep, using the concept of intrinsic time which is measured by the inelastic strain as well as Newtonian time, both of which are irreversible.

## **2.7 Creep-plasticity interaction and unified models**

The characterization of material behaviour at elevated temperatures plays an important role in the design of structures such as in hot sections of modern jet engines and other power plants. The ASME

code (1974) defines acceptable levels of stress and strain in critical components of power plants operating at elevated temperatures. The severe mechanical environment may often cause these structures to operate near or beyond the yield limit of the material. Consequently, a unified theory of creep and plasticity, applicable to cyclic loading, is often desirable.

Inelastic deformation at elevated temperature is complicated, because creep-plasticity interaction, recovery of hardening, and so on may take place.

For taking into account creep-plasticity interaction, it is usual to assume unified constitutive models, in which creep strain and plastic strain are regarded as inelastic strain identically (eg, Miller, 1976; Robinson et al., 1976; Hart, 1976; Chaboche, 1977; Krieg, Swearingen, and Rhade, 1978; Cernocky and Krempl, 1979, 1980; Walker, 1981). In such models, recovery of hardening due to thermal softening is expressed by incorporating recovery terms in the evolution equations of hardening variables on the basis of the idea of Bailey (1926) and Orowan (1946).

Unified constitutive models seem to be successful in describing inelastic deformation at elevated temperature, as seen from many applications; for example, Inoue, Imatani and Sahashi (1985), Moreno and Jordan (1986), Delobelle and Oytana (1987), Delobelle and L'excellent (1988), Freed (1988), Chaboche and Nouailhas (1989,b), Chan et al. (1988, 1989, 1990).

It is interesting to note that for modeling the viscoplastic behaviour of 316 stainless steel, Delobelle and Oytana (1987) assumed macroplastic strain for active loading and microplastic strain for unloading; the material hardens both isotropically and kinematically in the process of macroplastic strain, whereas only kinematic hardening takes place for microplastic strain. This assumption is based on their creep experiments at high and low stresses (Delobelle and Oytana, 1984).

The distinction between active loading and unloading was made also by Mroz and Trampezynsky (1984) and Hayhurst (1988). Assuming the memory of maximal prestress by Mroz (1981, 1983) they specified different evolution rules of back stress for active loading and unloading. The creep model proposed was then applied to creep under cyclic loading.

Strain aging plays an important role in some metals such as 304 and 316 stainless steel. Delobelle and L'excellent (1988) developed a unified model in which the hardening due to strain aging is taken into account, and applied it successfully to various inelastic deformations of 316 stainless steel in the temperature range of 20-700°C.

To evaluate inelastic constitutive models relevant to the material response under plasticity-creep interaction, bench-mark studies were conducted by the Subcommittee on Inelastic Analysis and Life Prediction of High Temperature Materials, JSMS (Inoue et al, 1985b, 1989a,b); 10 types of constitutive models were examined in comparison with experiments of 2<sub>1/4</sub>Cr-1Mo steel at 600°C under uniaxial and multiaxial loading conditions.

## **2.8 Similarities between models**

Similarities between models proposed on the basis of completely different concepts have been discussed in some works. It is important to acknowledge such similarities for understanding and developing further models.

Such discussion was given first by Marquis (1979) and Chaboche and Rousselier (1983). They showed equivalence between the nonlinear kinematic hardening rule of Armstrong and Frederick (1966) and a simple two-surface model based on bounding and yield surfaces. It is noted that these models were proposed independently; ie, the Armstrong-Frederick rule was formulated by incorporating a memory erasure (ie, dynamic recovery) term into the linear kinematic hardening rule, while two-surface models were developed by Dafalias and Popov (1975, 1976) and Krieg (1975) on

the underlying idea of the multisurface model of Mroz (1967). Further detailed discussion concerning the multisurface model, two-surface models, and the nonlinear kinematic hardening rule was given by Chaboche (1986).

Watanabe and Atluri (1986a,b), on the other hand, showed that the endochronic theory of Valanis (1980), with the kernel expressed in terms of the Dirac delta function and a series of exponential functions, results in the generalized nonlinear kinematic hardening rule (Chaboche and Rousselier, 1983), in which back stress consists of components obeying the rule of Armstrong and Frederick (1966). The endochronic theory of Valanis (1971, 1980) is one of the hereditary theories, and the nonlinear kinematic hardening rule belongs to internal variable theories. Watanabe and Atluri (1986a, b), furthermore, discussed that an appropriate choice of the kernel may result in the multisurface model of Mroz (1967) and the two-surface models of Dafalias and Popov (1975, 1976) and Krieg (1975).

Ohno and Wang (1990a) transformed the generalized nonlinear kinematic hardening rule by Chaboche and Rousselier (1983) into a multisurface form. It was thus shown that the multisurfaces generated by the transformation are nonintersecting, and that the translation of each surface relative to the surrounding surface obeys the rule of Mroz (1967). Then applying the transformation to time recovery terms and temperature-rate terms, they derived multisurface forms of these terms.

Chaboche (1989a) pointed out that the constitutive model developed at ONERA has similarities with other models such as the time-independent model by Ohno-Kachi (1986), the unified viscoplastic models by Walker (1981) and Krempl et al. (1986), and the differential form derived by Watanabe and Atluri (1986a, b) for the endochronic theory of Valanis (1980).

Although recent advance has been achieved in elaboration or improvement of existing models, some new concepts were presented, together with similarities with other models.

As seen in this review, the modeling has been developed so significantly. Thus highly sophisticated constitutive models which describe most of the phenomena needed for engineering applications are now available. However, further studies are still necessary for modeling complex phenomena such as non-proportional hardening and flow behaviour, ratcheting behaviour, thermomechanical behaviour and so on. Especially when they are coupled with strain aging, they cannot be predicted properly without elaboration and improvement of models.

## **2.9 Chaboche EVP model**

The current state of art of the modeling is mostly based on the concepts and models mentioned above.

In the present work, the Chaboche elasto-visco-plastic theory has been chosen to develop a material model able to describe the real behaviour for high temperature components subjected to cyclic loads. Chaboche EVP model allows to simulate, with reasonable accuracy, all the essential mechanical behaviour of Nickel base superalloy in the temperature range in which components, as gas turbine blades, normally work.

This material model is a generalized implementation of elastic, elastic-plastic or visco-plastic, and multi potential constitutive equations. The model is constructed entirely using object “bricks”. For the moment, the model will be constructed using an elasticity object, a number of “potentials” and

interactions between the potentials. Potentials represent inelastic dissipations, which describe the evolution of independent inelastic deformation mechanisms.

Hardening mechanisms are modelled with objects within the individual potentials (type of hardening depending on the type of potential) and are thus not yet specified. This behaviour is essentially a manager of sub-model objects, and will be discussed in general terms about the permissible variables.

The model's internal variables are determined by the sub-objects, which have been selected by the user. The general storage form includes variables, which are "global" to the material laws, and therefore form relations with the imposed (observable) variables or apply to all the potentials. Each potential may additionally contain "parameter" variables, which do not have associated forces, and "hardening" variables, which do have associated forces. The distinction concerns the form of interaction, which is possible.

### 2.9.1 Constitutive Laws

In this model, total strain  $\varepsilon_{to}$  can be divided into the following terms:

$$\varepsilon_{to} = \varepsilon_{el} + \varepsilon_{th} + \varepsilon_{pl} \quad (2.13)$$

In which:

$\varepsilon_{el}$  = elastic strain

$\varepsilon_{th}$  = thermal strain

$\varepsilon_{pl}$  = plastic or inelastic strain

In the same way, total strain rate can be divided into the following terms:

$$\dot{\varepsilon}_{to} = \dot{\varepsilon}_{el} + \dot{\varepsilon}_{th} + \dot{\varepsilon}_{pl} \quad (2.14)$$

Where overwriten symbols represent time derivatives of the terms.

In the proposed EVP Chaboche model, the plastic strain rate is  $\dot{\varepsilon}_{pl}$  expressed as:

$$\dot{\varepsilon}_{pl} = \dot{\lambda} n \quad (2.15)$$

With the Norton law:

$$\dot{\lambda} = \left\langle \frac{f}{K} \right\rangle^n \quad (2.16)$$

being:

$$n = \frac{3}{2} \frac{\sigma' - X'}{J_2(\sigma - X)} \quad (2.17)$$

Where  $f$  is the effective tension *von Mises Criterion*:

$$f = J_2(\sigma - X) - R \quad (2.18)$$

In the overwritten equations, the apexes quantities indicate the deviatoric component of tension:

$$\sigma'_{ij} = \sigma_{ij} - \frac{1}{3} \sigma_{kk} \delta_{ij} \quad (2.19)$$

According to the following definitions:

- Stress first invariant (or linear invariant):

$$\sigma_{kk} = \sigma_{11} + \sigma_{22} + \sigma_{33} \quad (2.20)$$

- Kronecker's delta or unit tensor:

$$\delta_{ij} = \begin{cases} 1, & i = j \\ 0, & i \neq j \end{cases} \quad (2.21)$$

- Stress second invariant (or Von Mises Equivalent Stress)

$$J_2(\sigma - X) = \sqrt{\frac{3}{2} (\sigma_{ij} - X_{ij}) \cdot (\sigma_{ij} - X_{ij})} \quad (2.22)$$

The stress tensor  $X$  represents *kinematic hardening*, and corresponds to the stress variation in the elastic dominion.  $X$  is called *back stress* too.

In Chaboche elasto-visco-plastic model kinematic hardening rule is non linear and is expressed through the **Armstrong-Frederick non-linear law**:

$$X = \frac{2}{3} C \alpha \quad (2.23)$$

$$\dot{\alpha} = \dot{\lambda} \left[ n - \frac{3}{2} \frac{D}{C} X \right] \quad (2.24)$$

This is the way that the stress tensor  $X$  (back stress) has been correlated to the strain tensor  $\alpha$  (back strain).

The scalar stress  $R$  represents isotropic hardening, and corresponds to a variation of the indicated radius into the elasticity domain.

Figure 2.2 - Isotropic deformation field sketch

In the EVP model proposed by Chaboche, we find isotropic hardening defined as a constant:

$$R = R_0 \quad (2.25)$$

In order to obtain a visco-plastic formulation that can be considered valid within a wide strain rate range, using an unified complete model, the Chaboche model introduces a multipotential plasticity/visco-plasticity formulation. For this reason, plastic deformation is divided into two different terms:

$$\varepsilon_{pl} = \varepsilon_{evr} + \varepsilon_{evl} \quad (2.26)$$

With:

$\varepsilon_{evr}$  : visco-plastic deformation for high strain rates

$\varepsilon_{evl}$  : visco-plastic deformation for slow strain rates

Both strain potentials have got visco-plastic features, their strain functions depend directly from time. The first potential has got a yielding point and an hardening rule. The second one, instead, give us a creep evolution mechanism including neither hardening nor yielding.

In this way, the first potential will give:

$$\dot{\varepsilon}_{evr} = \dot{\lambda}_r n_r \quad (2.27)$$

With:

$$\dot{\lambda}_r = \left\langle \frac{f_r}{K_r} \right\rangle^{n_r} \quad (2.28)$$

$$n_r = \frac{3}{2} \frac{\sigma' - X'}{J_2(\sigma - X)} \quad (2.29)$$

$$f_r = J_2(\sigma - X) - R_0 \quad (2.30)$$

In this way we will have:

$$\dot{\varepsilon}_{evr} = \left\langle \frac{J_2(\sigma - X) - R_0}{K_r} \right\rangle^{n_r} \frac{3}{2} \frac{\sigma' - X'}{J_2(\sigma - X)} \quad (2.31)$$

The first potential (usable for high strain rates) will result dependent from these parameters:

$n_r, K_r$ , that define Norton's Law

$C, D$ , that define kinematic Hardening

$R_0$  (yielding point), that defines isotropic hardening

The second potential will give:

$$\dot{\varepsilon}_{evl} = \dot{\lambda}_l n_l \quad (2.32)$$

With:

$$\dot{\lambda}_l = \left\langle \frac{f_l}{K_l} \right\rangle^{n_l} \quad (2.33)$$

$$n_l = \frac{3}{2} \frac{\sigma'}{J_2(\sigma)} \quad (2.34)$$

$$f_l = J_2(\sigma) \quad (2.35)$$

In this way, user will obtain:

$$\dot{\varepsilon}_{evl} = \left\langle \frac{J_2(\sigma)}{K_l} \right\rangle^{n_l} \frac{3}{2} \frac{\sigma'}{J_2(\sigma)} \quad (2.36)$$

The second potential (vailid for slow strain rates) will be defined by the two following parameters:

$n_l$ ,  $K_l$ , that define the well known Norton's Law.

### **3 User-defined Material Models - Methods of Implementation in FEM software**

#### **3.1 Introduction**

Plastic/Visco-plastic deformation in metals is a very complex phenomenon originating from highly nonlinear dynamical processes associated with microscopic defects, such as dislocations that tend to self-organize in the form of patterns, resulting into a heterogeneous field of deformation at the micro-scale although the overall macroscopic field is thought to be homogeneous.

Although there has been a tremendous effort to understand work hardening/strain softening and associated material instability phenomena, this research area is still in a parlous state, and rife with controversy. This is due to the difficulty of carrying out truly definitive experiments on critical aspects of the evolution of the dislocation structure. However, more important have been the immense theoretical difficulties of dealing with large numbers of dislocations and defects. Nevertheless, it is well understood that plastic deformation and strengthening in metals can be related to a number of heterogeneous patterns, such as dislocation cells, slip bands, micro-shear bands, persistent slip bands and dislocation tangles, which are critical for material properties.

The understanding of high-strain-rate behaviour of metals is essential for the modelling and analysis of numerous processes including high-speed machining, impact, penetration and shear localization. Thus, a desirable goal in constitutive modelling is to develop models which are widely applicable and capable of accounting for complex paths of deformation, temperature and strain rate which represent the main requirements of large deformation problems. The intended applications of the model as well as the availability and ease in obtaining experimental data specify the degree of complexity of the constitutive model.

Moreover, the degree of success of the model mainly depends on the flexibility and simplicity of determining material constants from a limited set of experimental data and capturing the important aspects of static and/or dynamic behaviour, besides being mathematically and computationally accurate.

In this chapter, it will be provided an overview of methods for implementing user-defined models in FEM software (codes based on Finite Element Method).

Finally, it will be explained how the Chaboche EVP model, chosen for the present applications, will be implemented in ANSYS code (FEM software used in this work) for executing nonlinear analysis on structural components.

#### **3.2 Methods for user-defined model implementation**

Large-scale finite element numerical simulations provide a feasible approach for assessing the performance of inelastic structural components operating under complex thermo-mechanical and multiaxial loading conditions.

The global solutions for any discretized finite element model are typically achieved, from the computational point of view, by an increment iterative procedure (e.g., Newton-Raphson technique).

The mathematical forms, accuracy and stability properties of a selected integration procedure will directly affect the accuracy and efficiency of the overall finite element solution. The development of stress integration algorithms with improved performance has received considerable attention in the recent literature on computational plasticity and visco-plasticity. In this regard, due to their stability and wide range of applicability, a number of well-established implicit schemes of time integration have been attracted the attention of many authors for plasticity and visco-plasticity (Simo and Taylor, 1985, Simo, 1991; Simo and Miehe, 1992; Freed and Walker, 1993; Saleeb and Wilt, 1993; Bathe, 1996).

For solving initial-boundary value problems, the stress state must be calculated by integrating a system of ordinary differential equations. In the framework of numerical methods like the finite element method, the system of differential equations is numerically solved by an appropriate integration scheme. In the framework of implicit finite element methods, the most popular strategy to integrate plastic or visco-plastic models is the backward Euler scheme (see e.g. Hartmann et al., 1997; Simo and Miehe, 1992; Simo and Hughes, 1998) as well as the exponential algorithm (see e.g. Miehe and Stein, 1992; Simo, 1993), which was originally proposed in finite visco-plasticity by Weber and Anand (1990).

The exponential algorithm has the advantage that the incompressibility of the inelastic deformations is always fulfilled. In contrast to this, the backward Euler method does not preserve the plastic incompressibility at finite step sizes. Consequently, the backward Euler scheme leads to incommensurate errors if large step sizes are applied (see e.g. the numerical studies in Tsakmakis and Willuweit (2003)). In Simo et al. (1985), Simo and Miehe (1992) and also in Luhrs et al. (1997) the error is eliminated due to an additional assumption, which leads to a cubic equation for a scalar-valued variable.

A number of material-related factors can cause structure's stiffness to change during the course of an analysis. Nonlinear stress-strain relationships of plastic, multilinear elastic, and hyperelastic materials will cause a structure's stiffness to change at different load levels (and, typically, at different temperatures). Creep, visco-plasticity, and viscoelasticity will give rise to nonlinearities that can be time-, rate-, temperature-, and stress-related. Swelling will induce strains that can be a function of temperature, time, neutron flux level (or some analogous quantity), and stress.

Any of these kinds of material properties can be incorporated into an ANSYS analysis using appropriate element types or a special material model. Nonlinear constitutive models are not applicable for the ANSYS Professional program.

### **3.2.1 *Object oriented software, modules and classes***

Method of modelling chosen in the actual work is based on aided object oriented programming and design. By the use of advanced programming languages (C++, Fortran 90) and programming, customizing and interfacing of API (*Application Programming Interfaces*) by software dedicate to material-analysis, it is possible to create and manage material library of assembling objects and classes.

The most advanced software, nowadays, are programmed and compiled using tools that can be assimilated with boxes. In each box, user can find useful tools (in this case constitutive equations of material behaviours). These boxes, to be versatile and usable for many purposes, have to be provided with *user programmable features* that, on one side, have to be able to interface the program with the outer world, while on the other one should be able to provide user-friendly commands and scheme to allow user building his functions.

In particular, *user programmable features* allow creating subroutines that interact with FEM solver. In this work, USERMAT is the subroutine containing material constitutive laws. Solver recalls it, at each integration point and for each equilibrium iteration. Inputs for each cycle are states variables, stresses, strains, strain increments and time variable. Output of each cycle is the Jacobian Material Matrix (stress, strain) at the end of each time increment.

This is allowed by using modular software for creating objects and classes to associate each one. This is almost the same structure for all modular software that are used for material model simulations.

### 3.2.2 Z-Mat

Z-Mat is the software used in the present work to develop a user-defined material model to be implemented in a FEM code, for performing elasto-visco-plastic analysis on structural components.

The Z-Mat product is mainly a library of material behaviour routines (constitutive equations), which can be interfaced with FEM software, and its supporting utilities. In contrast with other FEM software products however, Z-Mat is built on C++ with a strong object-oriented design, and many utility programming classes for advanced tensorial mathematics. Such advanced program design techniques have enabled the software to be enormously extensible, on many different levels of sophistication. In developing extensions to Z-Mat, a user can make new behaviours using the many abstract "material model building bricks" to create a modular, flexible model based on fundamentals.

For final use, it then lets the different implemented "bricks" define the specifics. That is to say, the user always chooses the final model form (e.g specific evolution or state equations) in the input file, after development is finished. In that way, each model is really a "model class" or framework within which a user has a high degree of flexibility. One can also add to the "types" available for these building bricks. This allows extending the capabilities of every model using that particular abstract "type".

The program itself is organized in different modules. In Figure 3.1, it is introduced a schematic view of Z-Mat modules:

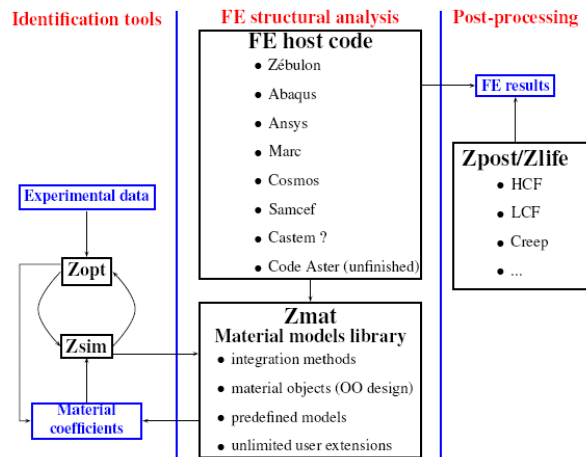

Figure 3.1- Z-Mat modules

The modules presented in the Figure 3.1 are briefly introduced, while for more detailed information, it cross-references to Z-Mat handbook.

Z-set is a FEA (Finite Element Analysis) solver, generally used for non-linear analyses, whose main feature is flexibility and capability to model innovative material models. Z-set has been designed to support the complete characterization process of materials including the capability to perform structural analysis, allowing the creation and utilization of robust and reliable material models.

Here is reported a brief description of the modules used within the scopes of this activity:

- **Z-Mat** is a dynamic library that extends the material modelling capabilities of FEM codes and provides a more flexible, object-oriented interface for developing user models. There are a large number of proven constitutive equations built into the library, including sophisticated models for plasticity, visco-plasticity, coupled plasticity-visco-plasticity, crystallographic plasticity, and creep, brittle and ductile damage. The nature of the library also allows all these models to be simultaneously available from a centralized location, so the user is not obliged to copy a large umat.f file to each calculation directory. Due to the modular design, the user can also build new user models from the input file, simply by combining several types of yield functions, flow rules and hardening rules. For example, plasticity-visco-plasticity does not exist as a predefined model; In this case, user can fabricate in the input file a material model to combine simultaneously time-independent and visco-plastic strain components.
- **Z-Sim** is a small simulator, allowing the user to load any representative volume element (RVE) in terms of mixed stresses and strains instead of forces and displacements, which allows fast simulation of material tests without FEA. Note that the material model code is shared 100% between the simulation and FEA. Functionality is also available to plot yield or damage (actually any potential) n stress space, at different points in the loading history. This tool is used to simulate material conditions under cyclic thermo-mechanical loads in order to understand and compare its behaviour. For example, a simulation can be performed in order to simulate material's stress relaxation under creep-like conditions.

- **Z-Optim** Optimization including several classical methods such as SQP, simplex or Levenberg-Marquardt, and genetic algorithms. In connection with Z-Sim this is a powerful tool for the identification of material parameters, while keeping exactly the same user interface as Z-Mat and Z-Sim. The optimal parameters can be determined through a process of least square minimization process using a set of experimental curves for reference and the simulated ones.
- **Z-Post** is a module to manage FEM results data post-processing execution and operations. It can be used to evaluate damage from fatigue and creep with the aim of calculating life of a structural component. It has interfaces and subroutines to be able to read results file from many FEM software.
- **Z-Ansys** is a bunch of tools that allow executing advanced and complex FE analyses, oriented to manage much material behaviour, utilizing ANSYS. This module uses a dynamic library of materials in order to extend ANSYS capabilities to model different material behaviours. It has a simple and powerful interface to develop new material models. It is linked directly to Z-Mat, Z-Sim and Z-Opt.

In the following periods, there will be described briefly how constitutive equations can be arranged in order to obtain the material card useful for an elasto-visco-plastic analysis.

In a Finite Element code, constitutive equations are used at each integration point to simulate material behaviour. Z-Mat adds capability by providing advanced constitutive equations based on the rigorous thermodynamic state variable formulation.

The primary numerical task for material simulation code for FEA calculations is to provide the value of the stress tensor and the state variables at the end of a loading increment, knowing the values at the beginning of the increment and a trial strain increment. More precisely, we can define an “object” BEHAVIOR as the collection of:

- Primal prescribed variable (e.g. strain) and dual (associated) variable (e.g. stress).
- Set of state dependent variables  $V$ .
- Set of auxiliary variables,  $A$ , not necessary for the computation, but used in the post-processing.
- External parameters,  $P$ , prescribed by the user and acting like an external load (e.g. temperature in a mechanical uncoupled calculation).
- Material parameters,  $M$ , to be identified for each material.

The constitutive equations are normally expressed as a first order ordinary differential system (ODE), the derivative of the state variables being defined as functions of the prescribed primal variable, of  $A$ ,  $P$  and  $M$ . The integration of this system can be made by explicit and implicit methods. Both techniques are included in Z-Mat as follows:

- Runge-Kutta method with automatic time stepping.
- Modified midpoint (q-method), solved with a Newton algorithm.

The explicit integration is easier to implement, and therefore is used for fast prototyping. Implicit integration however demands the definition of the local Jacobian matrix defining the behaviour, which is a more complex affair, but the method is more robust for large time steps, as it provides the information needed to compute the global consistent tangent matrix, and therefore permit quadratic global convergence.

Z-Mat treats all model formulations in the most general sense, employing object-oriented design to achieve a high level of flexibility. With this approach, the models are described in terms of material building “bricks,” such as yield criterion, isotropic or kinematic hardening evolution, or visco-plastic flow. A model is much more powerful with this approach because all the different “brick” types can be combined by the user to effectively make new models at run-time. In fact, even the coefficients are generalized (abstracted), allowing constant values, tabular values, or c-type syntax functions.

There are two ways of using Z-Mat:

- User-mode
- Developer-mode

As many constitutive equations are already implemented in Z-Mat, most users can simply make use of those in their calculations. A small change in the ANSYS input file is necessary to access the Z-Mat library, and an external material definition file must be created.

The input file modifications must give the material name, which will become the name of an external material definition file to control Z-Mat. The number of state variables is also required. Z-Mat does not use any information regarding coefficients or material parameters from the ANSYS input. Any number of Z-mat materials is accepted in the same run.

#### *3.2.2.1 Z-Mat Material Behaviours*

Material behaviours are a set of constitutive equations that are built from fundamental “building bricks” of sub-models. There is widespread re-use of all these “bricks” between different behaviour models.

The most important concept is the notion of a class of permissible options, of which the user will choose one or more objects from that class in the material definition.

A class is an abstract notion of basic functionality. An example is the ELASTICITY class that handles the calculation of stress from a strain, usually employing a fourth order tensor of various modulus coefficients. Because of this very general function, many behaviour models allow for an ELASTICITY instance.

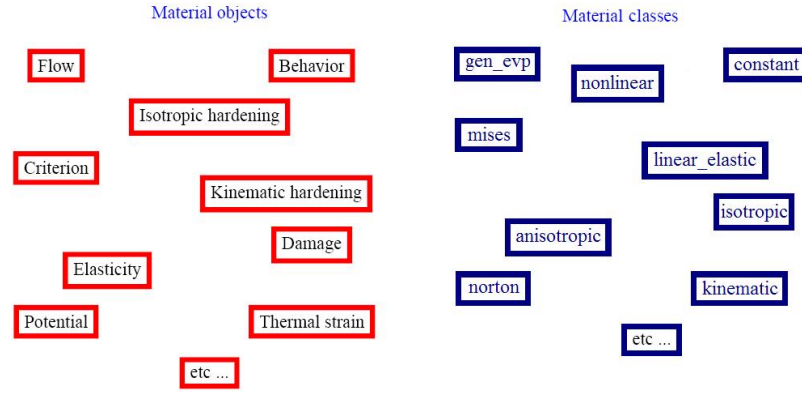

Figure 3.2- Z-Mat Objects and Classes

In turn, the elasticity class has many possible types that one can select in an elasticity object (isotropic, orthotropic, etc).

FEM software actually do not include in their libraries, the elasto-visco-plastic material model, since its complexity and high technology content, together with the limited computational capacity of most of common personal computers, did not permit its implementation.

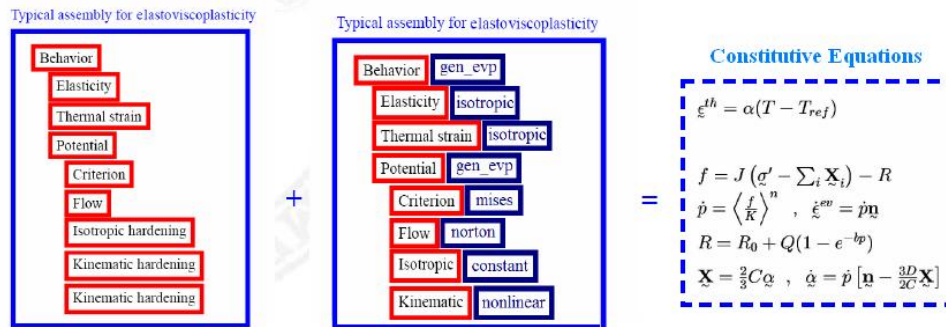

Figure 3.3- Z-Mat Objects + Classes = Constitutive laws

This is the reason why to implement such model, is necessary to use external software like Z-mat.

In Figure 3.3, it is shown a typical assembly for elasto-visco-plastic material behaviour. By the coupling of classes and objects, the constitutive equations that describe material behaviour have been selected. This modelling method has allowed implementing energy potentials, which, combined each other, describe the mechanism of inelastic dissipation and deformation evolution. Complex and superimposing hardening mechanisms are modeled by objects within individual potentials. In particular, in the example in Figure 3.3, material model shows an isotropic elasticity and thermal strain. The yield criterion chosen to describe plastic behaviour is the Von-Mises criterion and it has been used the Norton equation to calculate the viscous stresses and to describe the visco-plasticity. Finally to describe material hardening (and so the changes in yield surface) the superimposing of isotropic constant and kinematic nonlinear behaviour has been selected.

### 3.2.2.2 Material Files

The material coefficients are defined in a separate file. The material file is a standard ASCII text file of form similar to the main input file. Most instances where a material filename needs to be

specified allows an optional integer value for the instance of behaviour in that file, the default instance being the first. So, when a material file is opened, the program will search for the  $n^{\text{th}}$  occurrence of the keyword `***behaviour`, skipping all other data contained before. Frequently for example and verification problems, the material file is given in the same physical file as the referring input file for compactness and file management purposes.

Regardless of how or where the material file is located, the material file is a separate entity from the other input commands, with an independent command hierarchy starting at the `***`-level.

### 3.3 Z-Mat Chaboche model implementation

A particular form of the Chaboche model will be used, including thermal strain, non-linear isotropic hardening, linear and non-linear kinematic hardening, and some coefficients that vary with temperature. The behaviour model is only a framework for building up particular hardening/criterion/flow/etc combinations. The basic form of the model has been stated at the previous chapter, where the Chaboche constitutive laws for describing elasto-visco-plastic material behaviour have been defined in detail.

The model supports any number of kinematic hardening variables, and all coefficients in the model may be variable.

As shown previously, to start the material file, the `***behaviour` keyword must be used to indicate a generic behaviour object is to be created. All such objects will have a “class” keyword (here, `behaviour`), followed by a particular type of that class. For this model, the type is `gen_evp` for generalized elasto-visco-plastic. It should be noted that the asterisks in the Z-mat file indicate not only keywords, but a hierarchy of sub-commands. Thus all keywords of `**`-level are sub-commands of the `behaviour`, and the next `***`-level command (here `***return`) terminates the behaviour read. For this model, the elasticity matrix, thermal strain, and potential keywords are used.

The potential object is the most interesting one here, as it defines all the plasticity characteristics. The potential model chosen is again named `gen_evp` (but could be one of many others), and the characters following are an optional name for the potential. Output variables and coupling use this user-determined name.

The following is an example of Chaboche EVP model. It has been created by joining each applicable class with corresponding subclasses and tuning opportunely their instances and values.

Table 3.1 - Z-Mat elasto-visco-plastic material framework

The material file structure for the elasto-visco-plastic model consists of an elasticity object, an optional thermal strain object, an optional arbitrary number of potentials (without restriction on types), and a number of optional interaction objects:

A more detailed explanation of how it is possible to define a model of material behaviour through the coupling of classes and objects, it is provided in Z-Mat handbook.

The compatibility of objects with the other objects, and with the integration method will be investigated during the running of the problem. Because of the dynamic nature of these models however, it is often difficult to make any verification as to the physical meaning of a particular model combination. It is therefore strongly advised to observe the material behaviour on a single element. This allows experimentation of the integration method and selection of the output variables without performing costly full-scale calculations.

Multi-potential models are primarily used for cases of time independent plasticity in combination with visco-plastic deformation, or to assemble multiple crystalline deformation systems.

By default, there is no thermal strain, no inelastic deformation or any interactions. The optional names (name) given after each potential type are used as a means to specify individual potentials (for interactions), and in construction of the output variable names.

Normally, it is advised to use *ep* for a plastic potential name, and *ev* for a visco-plastic one.

## 4 Material Characterization

### 4.1 Introduction

The material behaviour characterization may be defined as: determining the material model response that better reproduces the observed experimental behaviour by using a design optimization framework.

In the present chapter it will be described the methodology of material characterization by:

- designing the experimental tests necessary to describe the aspects of material behavior that have to be investigated
- choosing the constitutive laws that better reproduce material behavior
- describing the iterative procedure for determining the coefficients of material model
- describing the procedure of model validation by means the comparison between experimental data and simulated ones.

The chapter is separated in five sections: theory, numerical methods, analysis of experimental data, limits of automatic procedure, design of experiments.

In the first section, it will be provided a theoretical description of material characterization tests. They can be summarized in tensile, fatigue and creep tests. It will be described the way in which the tests have to be performed, the type of specimen, the test machine and the main coefficients obtaining by them. Besides, it will be provided also a description of Chaboche elasto-visco-plastic material model chosen for the present applications, the constitutive laws and the meaning of each model parameter.

In the section of numerical methods, it will be described the methodology of material characterization: an iterative procedure of simulation of experimental tests and optimization of constitutive model coefficients through the comparison with the experimental data (by minimizing the least-square distance between experimental data and simulated curves). Besides, it will be described the procedure of model validation too.

In the third section, it will be analysed the experimental data. In particular, the described procedure will be applied for characterizing a Nickel base super-alloy, extensively used in high temperature components of jet engines and gas turbines for power generation.

In the fourth section, it will be described how the quality of performed experiments influences the material characterization process and the limits of an automatic characterization procedure will be highlighted.

The last section will provide guidelines for designing experimental tests able to identify optimized parameters set of material model.

## **4.2 Material Characterization – Theory**

### **4.2.1 Experimental tests**

Material characterization methodology is based on observed experimental results. Following it will be presented some basic elements on the types of tests, the machines and the modern measurement techniques likely to be used. Progress in electronics, automatic controls, digital measurements and in microprocessors has resulted in a radical transformation of the laboratories engaged in characterization of materials. One no longer has to be content with approximate measurements of a few quantities; since now it is possible to measure the evolution of any mathematically well defined variable precisely. The identification of complex models has thus become possible, but it requires numerical methods for the identification of nonlinear processes, which still belong to the domain of ‘heuristic’ techniques (Lemaitre and Chaboche, 1990)

Experimental tests represent the better way to obtain useful data and information on material characteristics. In fact, materials behaviour of components in service is strongly affected by their chemical mechanical and structural characteristics. This is the reason why it is important to know and well evaluate material properties.

The first step is the definition of the matrix of necessary experimental tests to the characterization of material behavior.

The present study has in particular dealt with the research of correlation between results of mechanical tests and fatigue, creep, yield stress and rupture sensitivity.

The complete tests matrix has to be designed in order to provide a sufficient statistical base to calculate minimum and average material curves and to obtain all the necessary experimental data for determining the material coefficients required by Chaboche elasto-visco-plastic model.

Tensile tests at various temperatures are used to determine base material mechanical properties such as Young’s Modulus, yield strength, Poisson’s ratio, etc.

Tensile tests at various temperatures and different strain rates are performed for determining the viscous effects and the viscosity parameters  $k$  and  $n$  (Norton’s flow parameters in elasto-visco-plastic Chaboche model)

LCF and HCF tests are performed in order to characterize material behaviour subjected to controlled-load cycle at various loading-rates. Some tests are performed in order to determine material hardening behaviour. Others have the objective to evaluate material stabilization laws.

High temperature creep tests are performed in order to evaluate creep behaviour of the superalloy. With more details on this subject, stress relaxation time is extracted from this type of test. Besides, creep strain is one of the most important data that it is possible to obtain from these tests.

### **4.2.2 Tensile Test**

Tests are performed according to the ASTM standards. A tensile test measures the resistance of a material to a static or slowly applied force. A machined specimen is placed in the testing machine and load is applied. A strain gage or extensometer is used to measure elongation. The stress obtained at the highest applied force is the tensile strength. The yield strength is the stress at which a prescribed

amount of plastic deformation (commonly 0.2%) is produced. Elongation describes the extent to which the specimen stretched before fracture. Information concerning the strength, stiffness, and ductility of a material can be obtained from a tensile test. Variations of the tensile testing include: room temperature, low temperature, elevated temperature (ASTM E21), shear, temperature and humidity, combined tension and compression, through thickness, true strain, notched tensile.

Tensile test results provide the following data:

- Tensile strength at yield.
- Tensile strength at break.
- Tensile modulus.
- Tensile strain.
- Tensile elongation and percent-elongation at yield.
- Tensile elongation and percent-elongation at break.
- $k$  and  $n$  coefficients of the monotonic curve (Ramberg and Osgood law) (P. Davoli et al., 2005)

The use of isothermal tensile tests at different strain rates allows evaluating material viscous behaviour: as a matter of fact, the difference between the curves at different strain rates gives the viscous stress. Knowing the viscous stress, it is possible to determine the Chaboche model coefficients,  $k$  and  $n$ , by Norton law.

Figure 4.1- Testing machine

Figure 4.1, gives a schematic drawing of a modern set-up for the tests, the essential elements of which are as follows:

- the system holding the heads of the specimen
- the dynamometer measuring the force applied to the specimen

- the transducer measuring the variation of length of the specimen
- the frame of machine, which should be as stiff as possible
- the heating device
- the device for applying the forces

During the test, the load is applied in specimen axis direction with constant and prefixed increasing rate (strain-controlled test).

The specimen presents an utilizable length at constant section joined with the extremities heads. Following (Figure 4.2) a typical specimen geometry:

Figure 4.2- Specimen for tension test - Definitions

In Figure 4.2, on the left a specimen with circular section, on the right a specimen with rectangular section.

The useful part of the specimen is constituted by an utilizable length  $L_0$  (Figure 4.3) and two lengths ( $C$ ) that allow to obtain a uniform stress field before of  $L_0$  beginning.

Figure 4.3- Specimen for tension test

In order to obtain comparable results, the specimens have to respect the following dimensions:

$$L_0 = k\sqrt{S_0} \quad (4.1)$$

Where  $S_0$  is the section and  $k$  is a coefficient that may be obtained by ASTM standards, in particular in case of specimens with circular section,  $L_0$  is assumed:

$$L_0 = 10 d_0 \quad \text{or} \quad L_0 = 5 d_0 \quad (4.2)$$

Where  $d_0$  is the diameter of the section.

The Figure 4.4 shows the curve  $\sigma - \epsilon$ , in which:  $\sigma_R$  is the maximum stress,  $\sigma_s$  is the yield stress. The elastic, plastic and striction fields are the indicated areas.

Figure 4.4- Curve Sigma-Epsilon

A stress-strain relation that describes non-linear material behaviour during plastic deformation is Ramberg-Osgood law (Lemaitre and Chaboche, 1990):

$$\varepsilon = \varepsilon_e + \varepsilon_p = \frac{\sigma}{E} + \left( \frac{\sigma}{k} \right)^{\frac{1}{n}} \quad (4.3)$$

In the relation (4.3) the elastic and plastic contributions are considered separately. The parameters  $n$  and  $k$  are two material constants:  $n$  is the strain hardening exponent and its value can vary between 0.005 and 0.4, while  $k$  is the  $\sigma$  value obtained for  $\varepsilon = 1$ .

Both parameters have to be determined experimentally using the  $\sigma$ - $\varepsilon$  value obtained by mean tensile tests.

Generation and mobility of dislocations are processes that require time to develop. Higher is the strain rate,  $\dot{\varepsilon} = \frac{d\varepsilon}{dt}$ , higher is material instability to flow with plasticity and its apparent elastic limit (Figure 4.5).

The tensile behaviour of the metals with the increasing of strain rate is shown in Figure 4.5, where it is possible to observe the  $\sigma$ - $\varepsilon$  curves of a steel material at different strain rates. The strain-rate effect on material mechanical properties is more important when the tensile test is performed at high temperatures and when material behaviour is visco-elastic.

Figure 4.5 –  $\sigma$ - $\varepsilon$  curves of a steel material at different strain rates

### 4.2.3 Fatigue Test

In materials science, fatigue is the progressive and localized structural damage that occurs when a material is subjected to cyclic loads. The maximum stress values are less than the ultimate tensile stress limit, and may be below the yield stress limit of the material.

ASTM defines fatigue life,  $N_f$ , as the number of stress cycles of a specified character that a specimen sustains before failure of a specified nature occurs.

The process starts with dislocation movements, eventually forming persistent slip bands that nucleate short cracks. Fatigue is a stochastic process, often showing considerable scatter even in controlled environments. The greater the applied stress, the shorter the life. Fatigue life scatter tends to increase for longer fatigue lives. Damage is cumulative. Materials do not recover when rested.

Many factors affect the fatigue life of metal structures. These factors are grouped into four categories (W. Cui, 2002):

1. material factors
2. structural factors
3. loading factors
4. environmental factors.

The more common test to characterize material cyclic behaviour consists in loading in the axial direction a cylindrical specimen with strain-controlled alternating cycles at constant amplitude and frequency.

Load cycles are (Figure 4.6):

$$\varepsilon_a = \frac{\Delta\varepsilon}{2} \quad ; \quad \varepsilon_{\max} = +\varepsilon_a \quad ; \quad \varepsilon_{\min} = -\varepsilon_a \quad (4.4)$$

Where:  $\varepsilon_a$  is the controlled-strain,  $\varepsilon_{\max}$  and  $\varepsilon_{\min}$  are the maximum and minimum strains obtained during one cycle respectively. An other parameter for defining a load cycle is the strain ratio:

$$R_\varepsilon = \frac{\varepsilon_{\max}}{\varepsilon_{\min}} \quad (4.5)$$

For  $R_\varepsilon = -1$  the load is alternating symmetric.

At the increasing of number of cycles, material response changes until to a stabilized condition that remains until failure. During the transitory phase, some materials harden cyclically (increasing of stresses to obtain the controlled-strain). Other materials soften cyclically (decreasing of stresses to obtain the controlled-strain during the test).

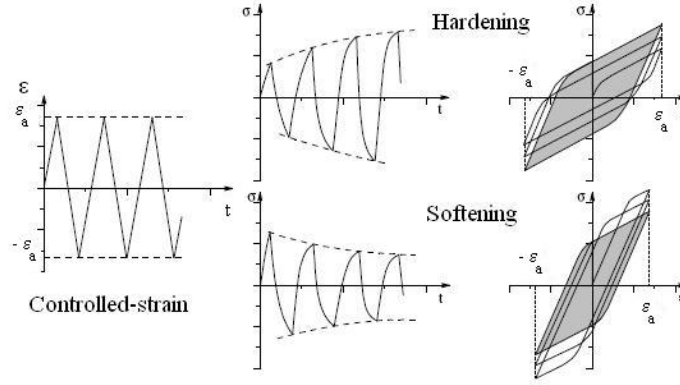

Figure 4.6 – Load cycles at controlled strain

In case of controlled-stress test, material response will be (Figure 4.7):

Figure 4.7 – Load cycles at controlled stress

Where  $\sigma_a$  is the controlled-stress and  $\sigma_{\max} = \sigma_a$  and  $\sigma_{\min} = -\sigma_a$  are the maximum and minimum stress obtained during each cycle respectively.

After the transitory phase, material response is stabilized. For convention, the stabilized cycle is  $N = N_f / 2$  (where  $N_f$  is failure life of specimen).

The parameters that define the cycle are:

- $\Delta\epsilon =$  strain
- $\Delta\sigma =$  stress

In Figure 4.8 an example of material hysteresis cycle. Elastic and plastic components of strain have been indicated:

$$\Delta\epsilon = \Delta\epsilon_e + \Delta\epsilon_p = \frac{\Delta\sigma}{E} + \Delta\epsilon_p \quad (4.6)$$

The slope of the line is the Young Modulus  $E$ .

Repeating the cyclic tests with  $R = -1$  at various controlled-strains (for example 0.1%, 0.2%, etc.), different stabilized cycles will be obtained. Inserting in a same graph the stabilized cycles at different controlled-strains and interpolating the vertex of these curves with Ramberg-Osgood equation, it is obtained a typical material curve: the cyclic curve (Figure 4.9).

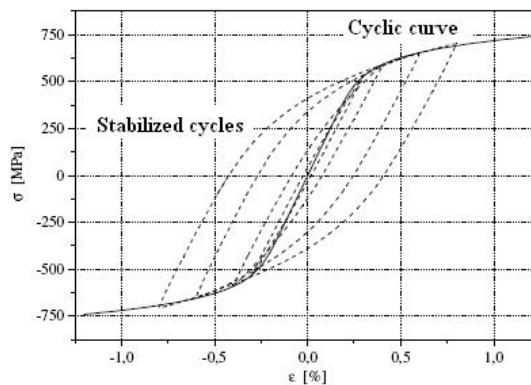

Figure 4.9 – Cyclic curve

Useful information about hardening or softening material behaviour are available by cyclic curve. Figure 4.10 shows cyclic and monotonic curves of some materials:

Figure 4.10- Examples of cyclic and monotonic curves

By the observation of the relative position between the two curves, it is possible to obtain the following information: cyclic hardening is verified when cyclic curve is upper monotonic one. On the contrary, cyclic softening is verified when cyclic curve is lower monotonic one.

#### 4.2.4 Creep Test

Creep is the tendency of a solid material to slowly move or deform permanently under the influence of stresses. It occurs as a result of long term exposure to levels of stress that are below the yield strength or ultimate strength of the material. Creep is more severe in materials that are subjected to heat for long periods, and near the melting point. Besides, creep always increases with temperature.

The rate of this deformation is a function of the material properties, exposure time, exposure temperature and the applied load (stress). Depending on the magnitude of the applied stress and its duration, the deformation may become so large that a component can no longer perform its function, for example creep of a turbine blade will cause the blade to contact the casing, resulting in the failure of the blade.

Creep is usually of concern to engineers and metallurgists when evaluating components that operate under high stresses or high temperatures. Creep is not necessarily a failure mode, but is instead a deformation mechanism. Moderate creep in concrete is sometimes welcomed because it relieves tensile stresses that otherwise may have led to cracking.

Unlike brittle fracture, creep deformation does not occur suddenly upon the application of stress. Instead, strain accumulates as a result of long-term stress. In fact, creep deformation is "time-dependent" deformation.

The temperature range in which creep deformation may occur differs in various materials. Generally, the minimum temperature required for creep deformation to occur is 30% of the melting point for metals and 40–50% of melting point for ceramics.

In modern jet engines, temperatures can reach up to 1400°C and initiate creep deformation in even advanced-coated turbine blades. Hence, it is crucial for safety's sake to understand creep deformation behaviour of materials.

Creep deformation goes through three stages:

Figure 4.11- Creep stages

By Figure 4.11 it may be observed that in the initial stage, or primary creep (I), the strain rate is relatively high, but it slows with increasing strain. The strain rate eventually reaches a minimum and becomes near constant. This is known as secondary (II) or steady state creep. This stage is the most understood. The characterized "creep strain-rate" typically refers to the rate in this secondary stage. Stress dependence of this rate depends on the creep mechanism. In tertiary creep (III), the strain rate exponentially increases with strain.

The material behaviour under high temperatures and mechanical loads is described through creep tests: a cylindrical specimen is subjected to a constant state of stress at a fixed temperature (Figure 4.12 – a). The strains are measured simultaneously by mean extensometers and the resulting variation in strain as a function of time is determined (Figure 4.12 – b). This also characterizes the hardening and the viscosity of material.

The strain variation, after the stress is removed (point B), corresponds to the recovery test. The partial strain recovery is indicated in Figure 4.12 (b)

Figure 4.12- Creep test and subsequent recovery

The results can be used to estimate the deformation behaviour of components that are exposed to long-term tensile stresses and high temperatures. These tests are quite often achieved for the determination of creep limits in order to be able to perform structural dimensioning or guarantee that the structure does not undergo any creep strain during operation.

It is also possible to perform a relaxation test during which strain is maintained constant (Figure 4.13 – a). By doing so, the stress is decreasing with time (Figure 4.13 – b). This gives information concerning the behaviour of structural components and the evolution of stresses in case of imposed strain. It is governed mainly by viscosity but also depends on the hardening induced by the initial load.

Figure 4.13- Relaxation test

The main information obtaining by creep curves is strain versus time. The strain is a function of three variable:  $\varepsilon = f(\sigma, T, t)$ . Often it is useful to know also the strain-rate versus time and versus strain:

$$\dot{\varepsilon} = f(\sigma, T, t); \quad \dot{\varepsilon} = f(\sigma, T, \varepsilon) \quad (4.7)$$

Summarizing, the tensile-creep modulus, the isochronous stress-strain curve, the creep-to-rupture curve and the relaxation behaviour can be determined from the creep curves.

#### 4.2.5 Constitutive laws

Once defined the experimental tests necessary to describe material behaviour, the next step of a characterization procedure is to choose the constitutive material model.

Chaboche-type models are particularly suited to integrate accurately a viscoplastic response under cyclic loading and in a wide range of temperature (the detailed description of the elato-visco-plastic Chaboche model has been provided at Chapter 2).

The basic equations (Azzouz et al., 2002) of the material model chosen for this study, are briefly summarized below, in terms of  $s$  (the deviator of the stress tensor  $\sigma$ ) and  $J(\sigma)$  (the Von-Mises invariant):

- Strain partition:

$$\varepsilon = \varepsilon_{el} + \varepsilon_v + \varepsilon_{th} \quad (4.8)$$

Where:  $\varepsilon_{el}$  is the elastic strain,  $\varepsilon_v$  is the plastic strain, and  $\varepsilon_{th}$  is the thermal strain.

- Plasticity criterion:

$$f(\sigma) = J(\sigma - X) - R \quad (4.9)$$

- Normality rule:

$$\dot{\varepsilon} = \dot{\nu} n \quad \text{with} \quad n = \frac{3}{2} \frac{s}{J(\sigma)} \quad (4.10)$$

- Norton flow:

$$\dot{\nu} = \left\langle \frac{f(\sigma)}{k} \right\rangle^n \quad (4.11)$$

- Nonlinear kinematic hardening:

$$X = \frac{2}{3} C \alpha \quad \text{with} \quad \dot{\alpha} = \dot{\nu} \left( n - \frac{D}{C} X \right) \quad (4.12)$$

- Nonlinear isotropic hardening:

$$R = R_0 + Q(1 - e^{-b\nu}) \quad (4.13)$$

In order to take into account both the variation of the elastic domain dimension (isotropic model) and its translation (kinematic non-linear model), it has been chosen the combined Chaboche model (Delprete et al., 2007).

It allows describing the hardening evolution for metallic material under cyclic loads.

In the above equations:

- the strain-rate dependence and the viscous effects are governed by a power law relation (equation 4.11).
- Cyclic hardening (evolution of the stress-strain loops from one cycle to the other) is characterized by equation 4.13, where  $R$  is an exponential function of the cumulated plastic strain  $\nu$ . In this expression,  $Q$  represents the amount of hardening between the first cycle and the stabilized cycle, and  $b$  is the rate of saturation.  
The equation 4.13 describes the variation of the elastic domain dimension.
- Kinematic hardening (equation 4.12) is then introduced to characterize the reversible hardening behaviour within each cycle. Integration of equation 4.12 also yields an exponential form, with  $C/D$  the asymptotic value and  $D$  the rate of saturation (note that sharper transition from elasticity to plasticity is obtained with higher values of  $D$ ).

For strain-rate controlled uniaxial tests, the maximum stress level obtained on the stabilized cycle can then be simply evaluated as:

$$\sigma = k(\dot{\varepsilon})^{\frac{1}{n}} + R_0 + Q + \frac{C}{D} \quad (4.14)$$

The elastic behaviour is described on the base of the hypothesis of linear isotropic elasticity (equation 4.8).

The hardening evolution in plastic field is described through two components:

- Isotropic hardening, that models the evolution of the elastic domain dimension by recalculating cycle by cycle the yielding stress;
- Kinematic nonlinear hardening that models the translation of the elastic domain by calculating the evolution of kinematic variable (back stress tensor).

The way to implement the elasto-visco-plastic Chaboche material model has been dealt at paragraph 3.3 and its basic framework has been shown at Table 3.1.

The identification of material coefficients for such sophisticated model is a complex process that necessitates efficient dedicated optimization tools. For the Chaboche model described above, there are seven coefficients to identify for each temperature (in addition of thermo-elastic parameters): the viscosity coefficients  $K$  and  $n$ , the isotropic hardening coefficients  $R_0$ ,  $Q$  and  $b$ , and the kinematic hardening coefficients  $C$  and  $D$ .

#### 4.2.6 Chaboche model coefficients

The involved coefficients have the following role:

- $R_0$  is the initial yield stress
- $C$  is the kinematic hardening modulus
- $D$  represents the rate with which  $C$  decreases at the increasing of plastic strain
- $Q$  is the asymptotic value of  $R$  variable, corresponding to the condition of stabilized hysteresis cycle. It is the cyclic hardening or softening.
- $b$  is the convergence rate to  $Q$  (rate for the stabilization)
- $k$  is the viscous stress for:  $\dot{\epsilon}^p = 1 s^{-1}$
- $n$  is the exponent of Norton flow and its value tends to one for high temperatures.

To better understand the physical meaning of previous coefficients, it is possible to observe an example of Chaboche model response of a typical engine material (Azzouz et al., 2002).

In Figure 4.14 is shown the first cycle and the stabilized cycle of an LCF strain-controlled test performed on a cast iron at the strain rate:  $\dot{\epsilon} = 10^{-4}$

The coefficients values of Chaboche model are indicated in the following table:

<b>R0</b>	<b>Q</b>	<b>C</b>	<b>D</b>	<b>k</b>	<b>n</b>
100	100	60000	600	500	8

Table 4.1 – Coefficient values of Chaboche model

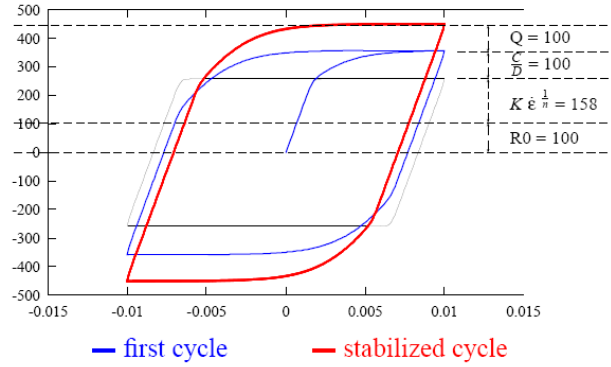

Figure 4.14- Chaboche model response of a typical engine material

By observing the Figure 4.14, it is possible to identify the coefficient  $R_0$  with the initial yield stress, the parameter  $Q$  with the difference between the stabilized and first cycles (it is just the amount of hardening).  $C/D$  is the asymptotic value of back stress. It is possible to verify the correctness of the coefficients set by the relation (4.14) for determining the maximum stress level on the stabilized cycle.

### 4.3 Material Characterization – Numerical methods

Knowing a mathematical model by its analytical expression, and obtaining a set of experimental results in which all the variables of the model have been activated, one is in the position to calculate the unknown coefficients which give the best representation of the experimental results.

#### 4.3.1 Methodology of characterization

As shown, the modelling of monotonic and cyclic behaviour requires the introduction of a large number of coefficients. Their identification for a given material is a difficult problem. The logical methods foresee three steps (Lemaitre and Chaboche, 1990):

- Choice of the characteristic tests and interpretation of the mechanical quantities:  $\sigma(t)$ ;  $\varepsilon_p(t)$ : this choice depends on the envisaged field of application:
  - initial loading
  - stabilized cycle
  - transient cyclic effects
- Choice of the modelling; in particular the choice of the form of the isotropic hardening which can incorporate the effects of cyclic accommodation. The comparison of an initial tension curve with the stabilized hysteresis loops (for the same load) is extremely helpful for detecting the changes in the size of the apparent elastic domain (variation of  $R$ ) or the changes in the apparent hardening modulus for the same strain (variation of  $D$ ).
- Identification of coefficients themselves: this is the most difficult step, but it is the one for which computer aided identification may be used.

The process for determining the material model coefficients starts by the identification of the constitutive equations (Chaboche model) and for each temperature:

- Calibration of the viscous effects on monotonic tests.

- Calibration of the isotropic and kinematic hardenings on cyclic tests.

The calibration of coefficients requires an experimental database that includes isothermal tests performed at different temperatures. Besides, a given model cannot be identified correctly unless a sufficient number of test results are available which embrace a significant range of variation of each parameter. Otherwise, it runs the risk of not determining one or more coefficients well enough.

For an identical material and model, it may be necessary to define several set of coefficients, each better suited to a domain of variation or to a load type, for example rapid transient loads, short-term loads, long-term loads and stationary loads.

The calibration of the coefficients of Chaboche material model is realized through the following steps:

The viscosity parameters  $k$ ,  $n$  and initial yield  $R0$  can be obtained using the strain-rate sensitive tensile tests. Besides, for optimizing the  $R0$  coefficient it is necessary using the first of the cyclic tests too.

The calibration of the kinematic hardening parameters  $C$  and  $D$  is obtained from the stabilized material response.

The isotropic hardening parameter  $Q$  represents the amount of hardening or softening of material and it is obtained from the stabilized and the first cycles of the material cyclic response.

The isotropic hardening saturation rate,  $b$ , have to be fitted on intermediate cycles.

In order to be able to determine the material coefficients coming from the experimental data, an iterative procedure has been designed.

The initial parameters, given by tentative, are fitted to the real curves through the processes of simulation and optimization that will be described in detail to the next paragraphs.

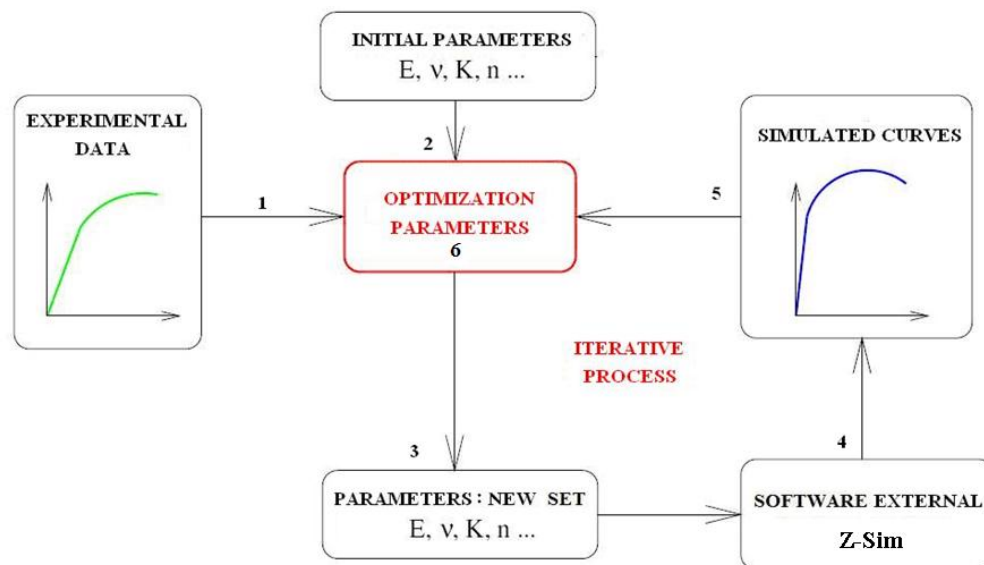

Figure 4.15- Procedure of material characterization

In the Figure 4.15, it has been synthesized the whole process applied in the present work for determining material model coefficients. The process starts by the definition of experimental tests necessary to describe the aspects of material behavior that have to be investigated.

Once the experimental data are available (1) and the constitutive laws have been chosen, an initial value, given by tentative, is assumed for each coefficient (2-3). Through an external software (4), the experimental tests are simulated (5) implementing the material model and through a least-squares method, the discrepancy between the experimental data and the numerically calculated values from the model is minimized (6).

One loop is not sufficient for realizing the best fit between the curves, for this reason the process is iterative type. In this way, a new set of parameters will be available by the comparison between experimental data and numerical ones and it will be used as initial set for the next loop.

The optimization process will be concluded when a good correspondence between the model response and the experimental data will be achieved.

The final set of parameters such obtained is the optimal coefficients set.

One of the principal difficulties associated with the use of complex constitutive equations to predict the behaviour of high temperature components is the number of parameters to be handled and the quality of experiments performed.

In fact, given a set of experimental results, it is always possible to find a function that represents it with an error not greater than the margin of uncertainty in measurements (the fitting process just described). Since the number of experimental points can be large, the fitting may require functions with a large number of representative coefficients.

On the other hand, a model that has the ambition of becoming a law, must possess a general character, so that while identified only by a restricted number of experiments, it is representative of other types of experiments with a predictive capability.

The totality of the situations verified by a model is its field of validity. This characterizes the goodness of the model and it is expressed qualitatively by the set of all possible variation histories of the variables and quantitatively by the range of the variations within which the model agrees with the physics.

The number of coefficients represents the price to pay since the difficulties of identification essentially lie in this number. It may be easy to identify say two coefficients by a 'hand procedure', but the identification of say five coefficients in a model will involve considerable numerical work; and the identification of say seven of them really belongs to 'computer-aided art'.

Therefore, to evaluate a model it is necessary to examine this relation of quality/price = domain of validity/number of coefficients clearly.

Both modelling and experiments ask for good identification tools, which are introduced in detail at the paragraph 4.3.3.

#### **4.3.2 Optimization method**

The standard form of the optimization problems is minimizing the function  $F$  (Michopoulos et al., 2006):

$$F = \frac{1}{2} \sum_{i=1}^N w_i \left( f(x, t_i) - y(t_i) \right)^2 \quad (4.15)$$

by changing  $x \in S$  such that:

$$g_j(x) \leq 0, \quad j = 1, n_g \quad (4.16)$$

has to be performed.

$F$  is the cost or objective function (scalar),  $g$  is a vector of constraints,  $x$  are the parameters to be optimized,  $t_i$  tags the experiment (experimental point increment, experiment number, time, etc), and  $w_i$  is the weight associated with experimental point  $i$ . A variable  $x$  (set of parameters) such that  $g_j(x) \leq 0, j = 1, n_g$  represents a feasible point. The cost function  $F$  is the least-square distance between experiments and simulations, and constraints  $g$  are used to bound and/or relate parameters with each other.

Optimal coefficient sets are obtained by minimizing the total error between numerous reference curves (experimental results documenting kinematic structural behavior) and simulated results. This method gives the best comprehensive fit of the material data while increasing confidence due to the numerous actual experimental data that contribute to the search for an optimal set of coefficients. The optimization process is controlled by the error minimization between the actual data and the simulated response and starts with an initial guess of all constants involved. The final values of these constants will be the outcome of the process.

### 4.3.3 Identification tools

When the number of parameters to be determined is high, it is necessary to turn to identification tools that allow applying the characterization methodology, described in the Figure 4.15, in an automatic way.

#### 4.3.3.1 Simulation tool

The optimal design parameters are chosen to minimize the least-square distance between experimental data and simulated curves generated by external software. The software used in the present work is the simulator module of Z-Mat package called Z-Sim.

It is connected to the optimizer and allows the user to load any representative volume element (RVE) under arbitrary stress or strain controlled conditions instead of forces and displacements, leading to fast and efficient simulations. It has an access to the integration methods, and leads to a very efficient integration of the constitutive equations: the integration time corresponds to one Gauss point only, and run more than 20 times faster than a single finite element.

The simulation procedure consists in writing an input file with the loading table, defined on the base of the test type to simulate. In the input file, it is defined also the number of load cycles and the

number of points to be stored in the output file. Material behaviour is defined in an ASCII file (such as described at paragraph 3.2.2.2) and automatically asked by the solver during simulation running.

Following, it is shown the results of some simulations made implementing the elasto-visco-plastic model of Haynes x (Haynes x is a material already characterized and made available by AVIO Propulsione Aerospaziale. It is not possible to show the material code and some of the experimental data, for reserve reasons on industrial data).

On the base of experimental data available, the following tests were simulated (Table 4.2):

Test Type	Strain rate [1/s]	Temperature [°C ]
Tensile	0.001	20 - 800

Table 4.2 - The type of simulated tensile test

The experimental tests were performed at constant strain-rate until specimens rupture. Following, the simulation results (Figure 4.16):

Figure 4.16- Simulated tensile tests at different temperatures

In the Figure 4.16 it is shown the simulated tensile curves ( $\sigma$ - $\epsilon$ ), where T800 (red data) and T20 (blue data) are tensile curves at  $T=800^{\circ}\text{C}$  and  $T=20^{\circ}\text{C}$  respectively.

Further simulations are the following (Table 4.3):

Test Type	Strain ratio $R_{\epsilon}$	Controlled-strain [% $L_0$ ]	Strain rate [1/s]	Temperature [°C ]
LCF	-1	0.3 - 0.5 - 0.7 - 0.9	0.01	20

Table 4.3 - The type of simulated LCF tests

The experimental LCF tests were performed at constant strain-rate and applying increasing controlled-strains. Following, the simulation results (Figure 4.17):

Figure 4.17- Simulated strain-controlled cycles at different total strain amplitude ( $R_e = -1$  )

In Figure 4.17, the first cycle of each load condition is shown.

The simulation results are then compared with experimental results to drive the optimization module, as it will be explained in detail at the next paragraph.

#### 4.3.3.2 Optimization tool

The optimization method, described at the paragraph 4.3.2, is implemented in the identification and optimization module of Z-Mat package, called Z-Opt.

Z-Opt is the optimization tool used in the present work to determine the parameters of the elasto-visco-plastic Chaboche material model.

The tool can handle any kind of constrained optimization problems and is useful for parameter identification. The optimal model parameters are typically chosen to minimize the least-square distance between a set of reference (i.e. experimental data) and simulated curves generated by any finite element code or any simulation tool.

All the optimization methods rely on a centralized method of evaluating the error function, and modifying the simulation using the variables being optimized. Error functions will be computed using a weighted sum of reference-simulation comparisons.

The Figure 4.18 shows a basic diagram of the interaction between the optimizer and any number of sub-simulations that generate the data to be compared with experimental results.

By observing the Figure 4.18, the process can be synthesized as follow: the variables of the optimization are specified in the optimization input file, where it is assigned an initial value to the variables and it is defined their range of variation.

These optimization files are templates for real files, which alter the simulation result. In fact, interfacing between the simulation program and the optimizer is simply done by creating a template for the input file containing the design parameters. The optimizer thus constructs new input files for the simulations, with the current optimization variables inserted in the appropriate locations. The error

functions are computed by the comparison between simulated curves and experimental ones. New variables values are available for the next loop until to achieve the best ‘fit’ between the curves and obtaining in output a set of optimized coefficient.

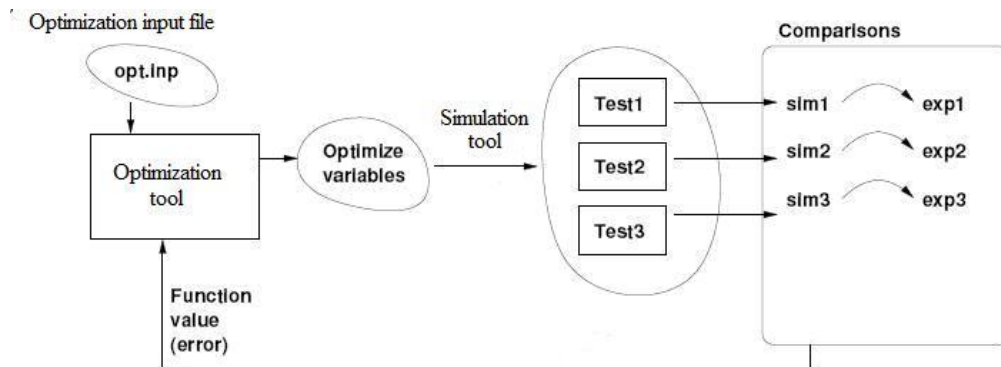

Figure 4.18- Optimization process

In general, the number of simulation-experiment comparisons will lead the problem to be over-constrained. It is the optimizer’s job then to find the best fit. If certain experiments are “important”, it is possible to employ weights on the comparisons functions to make them more dominant in the function evaluation. Besides, it is important to point out that robust results will be found with many diverse experiment conditions. Repeated experiments that merely provide a slight variation in response should be avoided, while complex experiments with many interacting effects should be emphasized.

The step-by-step procedure just described, foresees adding tests and the corresponding sensitive parameters progressively into the optimization loop. The previously calibrated coefficients provide good starting points for the next step, thus allowing the algorithm to escape local minima. At the end, all tests are added and all coefficients identified at the same time, thus yielding a good quality optimal set of coefficients.

Following, the results of some simulations and optimizations are shown.

Test Type	Strain rate [1/s]	Temperature [°C ]
Tensile	0.001	20

Table 4.4 - Tensile test

The results of the tensile test (Table 4.4) are shown in the Figure 4.19, where in the graph on the left it observes the result obtained by the initial simulation (assigning initial coefficients by tentative). (the blue curve is the experimental data – the red curve is the simulation)

As described at the paragraph 4.3.1, tensile tests allow optimizing the parameters:  $R_0$ ,  $n$ ,  $k$ . (unknown coefficients involved in this step).

The simulated curve is lower than the experimental one, so other computing loops are necessary to obtain the best result.

At the end of the optimization iterative process, the coefficients values have been optimized (by fitting the reference and the simulation) and in the graph on right, it observes the final result. The experimental curve and the simulation obtained by the optimized model are overlapped.

Figure 4.19- Optimized tensile test at fixed temperature.

Further simulation-optimization it is shown, test type is described in the Table 4.5:

Test Type	Strain ratio $R_\epsilon$	Controlled-strain [% $L_0$ ]	Strain rate [1/s]	Temperature [°C]
LCF	-1	0.9	0.01	400

Table 4.5 - LCF test

The results are shown in the Figure 4.20. In the graph on the left, it observes the result obtained by initial simulation (assigning initial coefficients by tentative). (Black curve is the experimental one – red curve is the simulation)

As described at the paragraph 4.3.1, LCF tests, allow optimizing the parameters  $R_0$ ,  $C$ ,  $D$ ,  $Q$ ,  $b$ . In particular, the parameters  $R_0$ ,  $C$ ,  $D$ , may be optimized through the first cycle. These are the unknown coefficients involved in this step.

After the first loop, there is not yet correspondence between the two curves, so other loops are necessary to obtain the best result.

At the end of the optimization iterative process, the coefficients have been optimized (by fitting the reference and the simulation) and in the graph on right it observes the final result. The experimental curve and the simulation obtained by the optimized model are overlapped.

Figure 4.20- Optimized LCF test at fixed temperature

#### 4.3.4 Validation of characterization methodology

The validation of procedure of characterization has been performed through the comparison between the experimental tests and the tests simulated in ANSYS code, implementing the external material model.

The first step is to realize FEM models of specimens used for experimental tests.

Subsequently, to apply boundary conditions to the model in way to reproduce the real test conditions.

To implement the external material model in ANSYS code and to simulate the same tests used for the material characterization.

By the comparison between the experimental data and material model response, it is possible to verify the predictive capability of the material model and to validate it.

Following, it is shown how the procedure just described has been applied in order to validate the coefficients set optimized at the previous paragraph (4.3.3.2).

Referring to the LCF test described in Table 4.5, it has been realized the FEM model of the specimen used to perform the experimental LCF tests for material characterization. Constraints and loads have been applied in way to simulate experimental test. The elasto-visco-plastic Chaboche model with the optimized coefficients has been implemented in ANSYS code and the simulation has been performed. A detailed description of validation process will be provided to the section 4.4 on the analysis of experimental data.

The ANSYS simulation of the test described in Table 4.5 and shown in Figure 4.20 has provided the following result:

Figure 4.21- Comparison between experimental LCF test (1<sup>st</sup> cycle) and the same test simulated in ANSYS code

The comparison, in Figure 4.21, shows a good agreement between the experimental data and material model response.

It has been performed the FEM simulation of the stabilized cycle of the same LCF test (Table 4.5), and by the comparison with the experimental stabilized cycle, again it has been verified a good correspondence between the data. The comparison is shown in Figure 4.22.

Figure 4.22- Comparison between experimental LCF test (stabilized cycle) and the same test simulated in ANSYS code

Repeating the procedure for the most significant tests used for the material characterization process, it is possible to validate the set of model coefficients.

#### 4.4 Material characterization – Analysis of experimental data

In order to face the more and more growing request of longer service intervals, more flexible operating cycles and higher performances (i.e. higher turbine inlet temperatures), the quantitative knowledge of the materials behaviour under complex loads and high temperatures is the key point to get a reliable and safe life assessment and extension.

For this reason, many companies are developing a wide experimental activity aimed to know and understand the high temperature behaviour of the most used base materials and coatings.

In the present section the methodology of material characterization will be applied to Renè 80, a Nickel base super-alloy which is used extensively in high temperature components of gas turbines for power generation.

This part of work has been developed in collaboration with Ansaldo Energia that has provided a set of experimental tests (tensile, LCF, creep) for the characterization of Renè 80. For reserve of industrial data, the axes values will be omitted by the figures, when it will be necessary.

Starting from the available experimental tests, the elasto-visco-plastic Chaboche model was developed.

In particular, the present section deals with the validation of the material model, the analysis of the problems associated to an insufficient data base of experimental tests (both for the variety and quality of available data) and it will be discussed in detail the limits of the automatic procedure of characterization.

#### 4.4.1 Material features

The material is a polycrystalline Ni-base alloy with a bimodal distribution of  $\gamma'$  phase. This alloy is used for hot components of gas turbines since it shows high mechanical properties, as well as microstructural stability during high temperature operation.

Renè 80 microstructure largely consists of a close packed face centred cubic matrix ( $\gamma$ ) which is made of Nickel and contains elements such as Cobalt, Chromium, Molybdenum, and Tungsten in solid solution. The second important phase is a FCC  $\gamma'$  phase, which is made of intermetallic compounds as  $\text{Ni}_3\text{Al}$  and  $\text{Ni}_3\text{Ti}$ . These compounds exist in form of hard precipitate particles in the  $\gamma$  matrix. The optimum volume fraction of  $\gamma'$  precipitates are about 50/60 %. The high temperature creep strength of this alloy is provided above all by the precipitate particles which resist to the motion of dislocations (E. Poggio et al., 2009).

The chemical composition of Renè 80 is:

Element	Ni	Cr	Co	Al	Ti	Mo	W	C	B	Zr
Renè80 [wt%]	bal.	14	9.5	3	5	4	4	0.17	0.015	0.03

Table 4.6 – Renè80 chemical composition

#### 4.4.2 Experimental tests

In this paragraph, it will be provided the main details about the available experimental data base of Renè 80. Experimental tests were designed for determining the coefficients of Chaboche EVP model.

##### 4.4.2.1 Tensile tests

Tensile tests were performed according the standards: UNI EN 10002 (2004), ASTM E 8.

The tensile tests matrix is the following:

Test Type	T [°C]	Strain rate [1/s]	Output	N° of Tests
Tensile	23-400-650-750-800-850-900-950-980	$10^{-2}$	$R_{p0.2}$ - $R_m$ -E-A%-Z%-n-k	18
	400-650-750-800-850-900-950-980	$10^{-4}$		16

Table 4.7 – Renè80 tensile tests matrix

By the Table 4.7: for each temperature and each strain rate, two tensile tests have been performed. The tests have been performed in controlled-strain and the outputs are respectively:

- Tensile strength at yield.
- Tensile strength at break.
- Young Modulus.
- Tensile elongation and percent-elongation at yield.
- Tensile elongation and percent-elongation at break.
- k and n coefficients of the monotonic curve (Ramberg and Osgood law)

The specimen used for the tensile tests is the following:

Figure 4.23- Tensile tests specimen

The machine test is a servo-hydraulic machine (type MTS by 10 tons) and it has been used an extensimeter of base 10mm. To calculate the percent-elongation at break, it has been used as reference the length  $L = 5d_0$  (where  $d_0$  is the diameter of the specimen utilizable length).

In Figure 4.24, it is shown the comparison between tensile tests performed at different temperatures and strain rate  $\dot{\epsilon} = 10^{-2} s^{-1}$ :

Figure 4.24- René 80 tensile tests at different temperatures and strain rate  $\dot{\epsilon} = 10^{-2} s^{-1}$

By observing the Figure 4.24: the tests have been performed until the specimen break. The yield stress has higher values between  $T=650^{\circ}\text{C}$  and  $T=900^{\circ}\text{C}$ , even if the absolute maximum value is obtained at  $T=23^{\circ}\text{C}$ . The maximum tensile strength at break is obtained at  $T=650^{\circ}\text{C}$

Besides, by the Figure 4.24 it is possible to observe an anomalous material behaviour at temperatures around  $T=800^{\circ}\text{C}$ . It shows an increasing of stresses with the increasing of temperature in the range of temperatures between  $T=650^{\circ}\text{C} - 800^{\circ}\text{C}$ .

The anomalous behaviour may be explained by a microstructural point of view, since the material changes its state around  $T=800^{\circ}\text{C}$ .

In Figure 4.25, it is shown the comparison between tensile tests performed at different temperatures and strain rate  $\dot{\epsilon} = 10^{-4} \text{ s}^{-1}$ :

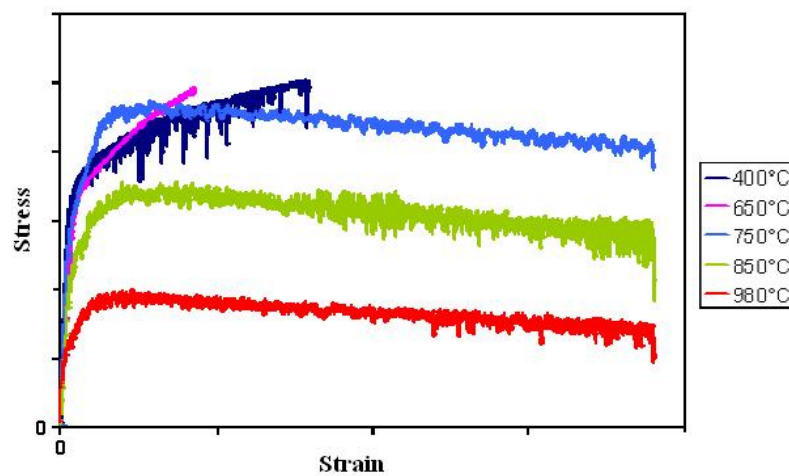

Figure 4.25- Renè80 tensile tests at different temperatures and strain rate= $10^{-4} \text{ s}^{-1}$

By observing the Figure 4.25: the tests have been performed until the specimen break. The yield stress has higher value at  $T=400^{\circ}\text{C}$ . The relative maximum of tensile strength at break is obtained around  $T=650^{\circ}\text{C}$

#### 4.4.2.2 LCF tests

LCF tests have been performed according the standards ASTM E 606.

The LCF tests matrix is the following:

Test Type	T [ $^{\circ}\text{C}$ ]	Strain rate [1/s]	Strain ratio $R_{\epsilon}$ Controlled-strain	Output	N° of Tests
LCF	400-800-900	$10^{-2}$	$R_{\epsilon} = -1$ ; 6 levels of $\Delta\epsilon$	Hysteresis cycle; $\sigma_{\max}$ and $\sigma_{\min} = f(N)$ ;	18
	900	$10^{-2}$	$R_{\epsilon} = -1$ ; 2 levels of $\Delta\epsilon - 20'$ hold time	cyclic curve; stabilized curve; $\epsilon\% = f(N)$	2

Table 4.8 – Renè80 LCF tests matrix

By the Table 4.8: the tests have been performed in controlled-strain. The type of load is alternating symmetric with strain-ratio:

$$R_\epsilon = \frac{\epsilon_{\min}}{\epsilon_{\max}} = -1.$$

For each temperature, one test has been performed for each level of  $\Delta\epsilon$ . This involves that only one valid test is available for each condition.

The levels of controlled-strain ( $\Delta\epsilon$ ) have been chosen such to have cycles of life between  $10^2 \div 10^4$ .

Besides, for the temperature  $T=900^\circ\text{C}$ , two tests have been performed with 20 minutes of hold time in compression, slope and down ramp at rate:  $\dot{\epsilon} = 10^{-2} \text{ s}^{-1}$ .

The specimen used for LCF tests is a cylindrical specimen and it is shown in Figure 4.26.

Figure 4.26- LCF test specimen

The machine used for the tests is a servo-hydraulic machine (type MTS 810). It is possible to observe in Figure 4.27, on the left an image of the test machine, on the right the test set up. The induction system (Power: 15 kW and variable frequency) shown in Figure 4.27, heats the specimen, the temperature is controlled through thermocouples and the elongation at break is measured by the extensimeter.

Figure 4.27- LCF test machine and test set up

The tests outputs are: number of cycles to failure,  $N$ , for each test,  $\sigma_{\max} = f(N)$  and  $\sigma_{\min} = f(N)$ , hysteresis cycles, isothermal curves  $\Delta\epsilon - N_i$ , and stabilized cycles.

In Figure 4.28 it is shown the fatigue curve at  $T = 800^{\circ}\text{C}$ : total controlled-strain versus number of cycles to failure, in logarithmic scale. In the same figure, it is shown also the equation obtained through exponential regression.

Figure 4.28- Fatigue curve at  $T=800^{\circ}\text{C}$

In the Figure 4.29, it is shown the hysteresis cycle obtained for the LCF test performed at  $T=900^{\circ}\text{C}$  and  $\Delta\varepsilon \% = 0.99$ . In particular, it is shown the first and the stabilized cycles, used in the material characterization process for determining kinematic and isotropic hardening coefficients of Chaboche model.

Figure 4.29- Hysteresis cycles - LCF test at  $T=900^{\circ}\text{C}$  and  $\Delta\varepsilon \% = 0.99$

Moreover, in order to know after how many cycles the material behaviour is stabilized, it is necessary to calculate the curves:

$$\sigma_{\max} = f(N) \quad \text{and} \quad \sigma_{\min} = f(N)$$

In fact, when the values of  $\sigma_{\max}$  and  $\sigma_{\min}$  do not change between the previous cycle and the next one, the material behaviour is stabilized.

In Figure 4.30, it is shown the curve  $\sigma_{\max}$  versus number of cycles obtained by the LCF test at  $T=900^{\circ}\text{C}$  and  $\Delta\varepsilon \% = 0.99$ . The material stabilization is achieved around to the 15<sup>th</sup> cycle. The decreasing of the maximum stress observed in the final part of the curve, is due to the fact that the test is performed until the specimen failure.

Figure 4.30 – Curve  $\sigma_{\max}$  vs N - LCF test at  $T=900^{\circ}\text{C}$  and  $\Delta\varepsilon \% = 0.99$  -

Finally, by the stabilized cycles, the cyclic curve of material has been determined such as explained at the paragraph 4.2.3, in order to evaluate the cyclic material response. In fact, by the comparison between the monotonic curve and cyclic curve (in particular observing the relative position between them) it is possible to evaluate the hardening (or softening) material behaviour. This is one of the first information necessary in the material characterization process.

In Figure 4.31, it is shown the material cyclic curve determined for  $T=800^{\circ}\text{C}$ :

Figure 4.31- Cyclic curve at  $T = 800^{\circ}\text{C}$

In particular, in Figure 4.31 the stabilized cycles peaks of the tests performed at different levels of controlled-strain have been interpolating with Ramberg-Osgood equation (4.3). The result is the cyclic curve.

#### 4.4.2.3 LCF - step tests

For determining the Chaboche model of Renè 80, LCF step tests are necessary in addition to the LCF traditional ones (LCF duration tests). Each specimen is submitted to steps of N cycles performed at increasing levels of controlled-strain ( $\Delta\epsilon_1 < \Delta\epsilon_2 < \Delta\epsilon_3 < \Delta\epsilon_4$ ) and two strain rates. At the end of steps the specimen have not to be failure since the material have to be submitted to a relaxation.

In the Table 4.9 the matrix of LCF step tests:

Test Type	Controlled strain	Cycles	Strain rate [1/s]	T [°C]		
				400	800	900
LCF - Step	$\Delta\epsilon_1$	20	$10^{-2}$	2tests	2tests	2tests
	$\Delta\epsilon_1$	20	$10^{-4}$			
	$\Delta\epsilon_2$	20	$10^{-2}$			
	$\Delta\epsilon_2$	20	$10^{-4}$			
	$\Delta\epsilon_3$	20	$10^{-2}$			
	$\Delta\epsilon_3$	20	$10^{-4}$			
	$\Delta\epsilon_4$	20	$10^{-2}$			
	$\Delta\epsilon_4$	20	$10^{-4}$			

Table 4.9 - Renè80 - LCF step tests matrix

The outputs of LCF step tests are the same of LCF duration tests. In addition, the stress relaxation curve is provided for each test condition.

In Figure 4.32 it is shown the result of LCF step test at T=900°C. In particular, it is shown the  $\sigma_{\max}$  and  $\sigma_{\min}$  curves versus the number of cycles.

Figure 4.32- LCF step test at T=900°C

In Figure 4.33, it is shown the stress relaxation curve obtained from the same LCF step test performed at T=900°C. The last level of controlled-strain was held constant for one hour, to obtain a stress relaxation.

Figure 4.33- Stress relaxation at T=900°C

#### 4.4.2.4 Creep tests

Creep tests were performed according the standards ASTM E 139, EN10291.

The creep tests matrix is the following:

Test Type	T [°C]	Controlled stress	Output	N° of Tests
Creep	800-850-900-950	5 levels of $\sigma$	$t_u$ ; $\epsilon=f(t)$ ; $\epsilon_R$ ; $A_R$ ; creep strain rate ; minimum strain rate	20

Table 4.10 - Renè80 – Creep tests matrix

The specimen is subjected to a constant state of stress and the resulting variation in strain, as a function of time, is determined.

Four temperatures and five levels of load were examined (Table 4.10). In particular, the range of temperatures has been chosen in way to be the most representative of the real conditions of the components during service. The levels of load have been chosen to have failure times well distributed in the range of interest (300-10000 hours).

The test outputs are (Table 4.10):

- Time to failure
- Creep curve: strain versus time
- Strain and elongation at break ( $\epsilon_R$  ;  $A_R$ )
- Creep strain rate and minimum creep strain rate.

Creep tests specimen is shown in Figure 4.34.

Figure 4.34- Creep tests specimen

Two extensometers have been used for monitoring the strain in the specimen utilizable length during the test. Three thermocouples have been applied along the axis of the specimen utilizable length to control the temperature.

The strain has been calculated by:

$$\varepsilon = \frac{\Delta l}{l_0} \quad (4.17)$$

Where:  $l_0$  and  $\Delta l$  are respectively the specimen utilizable length and its elongation during creep test.

The accumulated plastic strain has been calculated as follows:

$$\varepsilon_p = \varepsilon_{tot} - \frac{\sigma}{E} \quad (4.18)$$

Where  $\varepsilon_{tot}$  is the total strain cumulated during the loading phase.

Following, some results of creep tests.

In Figure 4.35, it is shown the time to failure measured for each test (for each level of load). The graph time to failure versus stress is in logarithmic scale and at different temperatures.

Figure 4.35- Time to failure versus stress for the four test temperatures

In the Figure 4.36, it is shown the creep curves obtained for  $T = 900^{\circ}\text{C}$  at the following levels of load:  $\sigma_1 = 130 \text{ MPa}$ ,  $\sigma_2 = 150 \text{ MPa}$ ,  $\sigma_3 = 160 \text{ MPa}$ . The Figure 4.36 shows strain% versus time.

Figure 4.36- Creep curves -  $T=900^{\circ}\text{C}$

Finally, in Figure 4.37 it is highlighted the creep primary stage of the three curves shown in Figure 4.36, for the creep tests performed at  $T=900^{\circ}\text{C}$ .

Figure 4.37- Creep primary stage of curves shown in Figure 4.36

#### 4.4.3 Elasto-visco-plastic behaviour model of Renè 80

Chaboche model described at paragraphs 2.9.1 and 4.2.5 was chosen for modelling the elasto-visco-plastic behaviour of Renè 80.

The viscoplasticity with isotropic and kinematic hardening combines plasticity and creep and allows taking into account of the rate dependence. Besides, it let stresses outside of yield relax if there is not further straining.

A multi-kinematic hardening mechanism was chosen (Lemaitre and Chaboche, 1990):

$$f(\sigma) = J(\sigma - \sum X_i) - R \quad (4.19)$$

In which the kinematic variables  $X_i$  are independent and obey to an evolution rule such that:

$$dX_i = \frac{2}{3} C_i d\varepsilon^p - D_i X_i dp \quad (4.20)$$

Where:  $\varepsilon^p$  is the present plastic strain and  $p$  is the accumulated plastic strain.

The necessity to introduce a multi-kinematic hardening mechanism was due to the wide range of changes in strain shown by LCF tests. In this case, one kinematic hardening mechanism was not sufficient to describe the transition from linear to nonlinear material behaviour. In fact, for very low strains, one recovered the linear case with a poor representation of the elasto-plastic transition and for high strains, the limiting value was reached very rapidly. For remedying to such deficiency, two kinematic hardening mechanisms were superimposed.

An example of the results obtained by the implementation of multiple kinematic hardening mechanisms is shown in the following figure:

Figure 4.38- Multi-kinematic hardening mechanism

In particular, the Figure 4.38 shows the superposition of two kinematic variables  $X_1$  and  $X_2$ , where the first one describes the linear case, for very low strains, and saturates rapidly. While the variable  $X_2$  saturates slowly and describes the transition from linear to nonlinear case, for high strains.

Two kinematic variables were chosen for the EVP model of Renè 80:  $X_1$  and  $X_2$ . Each of them covers a range of strain for smoothing out the transition from linear to nonlinear behaviour and modelling the short and long-range hardening mechanisms.

Besides, a kinematic hardening model with static recovery was chosen in order to take into account the time-dependent recovery of the hardening shown by material at high temperatures. This choice was also made since constant strain-rate was verified during creep tests. It was due to a balance of defect creations (hardening) and destruction (recovery). The implemented law is:

$$\dot{\alpha} = \dot{\lambda} \left[ n - \frac{3}{2} \frac{D}{C} X \right] - \frac{3}{2} \frac{X}{J(X)} \left( \frac{J(X)}{M} \right)^m \quad (4.21)$$

Where: the first term is the law that describes the nonlinear kinematic hardening introduced at the paragraph 2.9.1. The second term describes the static recovery through the coefficients  $m$  and  $M$ , which are added to the Chaboche model for each of the two kinematic hardening mechanisms considered.

For these reasons, the Chaboche model chosen for describing the elasto-visco-plastic behaviour of Renè 80 had a high number of parameters: seventeen coefficients.

The model parameters were obtained by starting from the experimental tests and using the Z-Mat identification tools (Z-Sim and Z-Opt), through an automatic procedure of characterization.

On the base of the available experimental data, the parameters were determined at the temperatures:  $T=400-800-900^\circ\text{C}$ .

At room temperature, experimental data were lacking. For this reason, the same data obtained at  $T=400^\circ\text{C}$  were assumed, and at the other temperatures the coefficients were interpolated, in order to simulate also other test conditions. Finally, a set of coefficients was obtained through the procedure of characterization.

#### **4.4.4 Validation of Renè 80 material model**

As explained at the previous section, in order to verify the capability of the model to simulate the real material behaviour, it was implemented in a FEM code for simulating the characterization tests.

The simulated curves were compared with the experimental ones.

##### **4.4.4.1 FEM simulation of LCF tests**

The first step was to realize the FEM model of specimen used to perform LCF tests (Figure 4.39 and Figure 4.40).

Figure 4.39- Specimen model - Areas

Figure 4.40- Specimen model - Mesh

The element type is the axial-symmetric element PLANE182 (2-D 4-Node Structural Solid), having two degrees of freedom (displacements in axial and radial direction).

FEM analysis was performed on utilizable length of the specimen and the following simplified model was realized (Figure 4.41):

Figure 4.41- Utilizable length FEM model

Figure 4.42- FEM model - Loads and Constraints

Since ANSYS code is not able to perform strain-controlled tests, the axial displacement that generates the test controlled-strain has been calculated (at the temperature and at the strain rate of the test) according the following equation:

$$\frac{l-l_0}{l_0} = \varepsilon \quad (4.22)$$

The displacement is applied in the nodes as indicated in Figure 4.42. In the same figure it is shown how the constraints have been applied too. The axial displacement of the nodes (as indicated in the Figure 4.42) is blocked in the direction of loading.

Some of experimental LCF tests were simulated in ANSYS.

Following the results of the simulation of LCF test performed at T=400°C,  $\Delta\varepsilon_{tot} = 1.189\%$  and total number of cycle N = 140.

The stress-strain curve was calculated in a node located in the centre of the FEM model, far from constraints.

By observing the experimental test, material behaviour stabilized after few cycles. The simulation was performed applying eleven load cycles.

In Figure 4.43, it is shown the curve strain versus time calculated in the node considered and in Figure 4.44 the curve stress versus time of the same node.

Figure 4.43- Time history of strain

Figure 4.44- Time history of stress

Following, in Figure 4.45 it is shown the comparison between the experimental first cycle and the simulated cycle. In Figure 4.46 the comparison between the stabilized cycles.

Figure 4.45- Comparison between the first cycle of LCF experimental test and the simulated one

Figure 4.46- Comparison between the stabilized cycle of LCF experimental test and the simulated one

The comparisons shown in Figure 4.45 and Figure 4.46 illustrate a good predictive capability of the model for the stabilized material behaviour, differently for the first cycle.

All the comparisons performed between LCF experimental tests and simulated ones have shown a good correspondence on the stabilized cycle, while differences have been highlighted on first cycle. In particular, the model response is not sufficient to describe correctly the transition from linear to non-linear material behaviour.

#### 4.4.4.2 FEM simulation of creep tests

The first step was to realize the FEM model of specimen used to perform creep tests (Figure 4.47 and Figure 4.48).

Figure 4.47- Specimen model - Areas

Figure 4.48- Specimen model - Mesh

The element type is the axial symmetric element PLANE182 (2-D 4-Node Structural Solid), having two degrees of freedom (displacements in axial and radial direction).

FEM analysis was performed on utilizable length of the specimen and the following simplified model was realized:

Figure 4.49- Utilizable length FEM model

Loads and constraints were applied as shown in Figure 4.50:

Figure 4.50- FEM model - Loads and Constraints

Some of experimental creep tests were simulated in ANSYS.

Following, in Figure 4.51, the results of the analysis that simulates the creep test performed at  $T=800^{\circ}\text{C}$  and  $\sigma = 290 \text{ MPa}$ .

Figure 4.51- Comparison between experimental creep test and simulated one

The creep curve (Figure 4.51), time expressed in hours versus strain%, was calculated in a node located in the centre of the FEM model, far from constraint.

The comparison, shown in Figure 4.51, illustrates a not sufficient predictive capability of the model for the creep material behaviour.

#### 4.5 Limits of the automatic procedure of characterization

The most important and difficult aspect of modeling material behaviour at elevated temperature is to obtain the required material functions for viscoplasticity and associated material parameters.

The complexity of this process typically stems from not only the variety in mathematical forms for the material functions, but also from the fact that given the material functions there is no unique set of material parameters for any given load path. Therefore, numerous iterations and difficult compromises

are required before a final set of material parameters (for the assumed material functions) can be obtained.

Traditionally, characterization has been accomplished through basic trial and error procedures (i.e., graphical and/or mechanistic) which attempt to fit the predicted response from the constitutive model to that response exhibited by the experimental test data. These approaches, however, are rather limited, difficult, and many times less than fruitful for more general and sophisticated constitutive models. This is particularly true when dealing with models that possess a very large number of material constants that:

- are often lacking in their direct physical interpretation
- may have vastly different magnitudes
- are highly interactive with each other.

Further complications also arise when a large number of experimental tests of various types under transient and/or steady-state conditions, are expected to be simulated.

Besides, a model must have a general character, so that while identified only by a restricted number of experiments, it is representative of other types of experiments with a predictive capability.

The totality of the situations verified by a model is its field of validity. The goodness of the model is expressed qualitatively by the set of all possible variation histories of the variables and quantitatively by the range of the variations within which the model agrees with the physics.

A given model cannot be identified correctly unless a sufficient number of test results are available, which embrace a significant range of variation of each parameter. Otherwise, one runs the risk of not determining one or more coefficients well enough.

The number of coefficients represents the price to pay, since the difficulties of identification essentially lie in this number and for this reason it is necessary to turn to the computer aided identification.

As shown previously, software tools as Z-Sim and Z-Opt have been developed to enable a design engineer to bridge this gap between constitutive theory and experimental test data, in which optimum material parameters have to be determined by minimizing the errors between experimental data and the correlated responses.

The main difficulties associated with the use of complex constitutive equations to predict the behaviour of high temperature components are:

- Number of parameters
- Quality of performed experiments

The aim of this part of work is to show the limits of an automatic procedure of material characterization and how the process is affected by the available experimental data.

#### ***4.5.1 High number of coefficients and problems of solution convergence***

One of the main difficulties found in the process of René 80 characterization was in the identification of the high number of model coefficients.

In this model, two potentials have been defined in order to take into account the different mechanisms of material deformation associated with a wide range of strain rates.

For the first potential:

- two coefficients for Norton law which describe the viscous behavior ( $K$ ,  $n$ )
- three coefficients for modeling the non linear isotropic hardening mechanism ( $R_0$ ,  $Q$ ,  $b$ )
- four coefficients for modeling the two nonlinear hardening kinematic mechanisms ( $C1, D1$  and  $C2, D2$ )
- four coefficients for describing the recovery of the hardening at high temperatures ( $m1$ ,  $M1$  and  $m2$ ,  $M2$ )

For the second potential:

- two coefficients for Norton law ( $K$ ,  $n$ )
- one coefficient for isotropic constant hardening ( $R_0$ )

Other two model coefficients are Young and Poisson Modulus for describing the linear elastic behaviour.

In these cases, it is strongly advised to use a step-by-step procedure of characterization, adding tests and the corresponding sensitive parameters progressively into the optimization loop. In such procedure, the previously calibrated coefficients provide good starting points for the next step, thus allowing the algorithm to escape from local minima. Finally, all tests have to be added and all coefficients identified at the same time, for obtaining a good set of coefficients.

In spite of a step by step procedure was applied, many problems of convergence of the optimization tool were verified.

Many coefficients in fact are strongly depending each other and, in absence of a good experimental data base, a non correct identification of one of them, implies the not convergence of the solution during the optimization process.

This has been verified during the identification of the parameters  $R_0$  and  $k$ . They represent respectively initial yield stress and viscous stress. For determining them, it is necessary an experimental data base which includes many tensile tests at different temperatures and strain rates. Later, it will be shown the available data were not sufficient. For this reason, it was not possible to optimize those parameters. Even forcing the tool and inserting "by hand" the real value of  $R_0$  (the initial yield stress read by the first cycle of the LCF test), it wasn't possible to obtain the optimized value of  $k$ , since the solution didn't converge.

#### **4.5.2 Quality and variety of experimental tests**

Further critical aspect on which to focus on the attention is to have at disposal a "correct" experimental data base.

A correct data base implies variety of experimental data not just quantity. In other words, if one only provides tensile data to the optimization tool for determining the coefficients of the model, one should not expect the model to be able to accurately predict both creep and relaxation response (since the time duration of these types of tests far exceeds that of a tensile test). Similarly, if one provides

only creep or relaxation data to the tool, one should not expect the model to accurately represent the typically shorter time domain tensile behavior of the material.

Besides a correct data base means also dependable experimental data, proved by a sufficient number of repetitions for each test.

A detailed analysis of the available experimental data base was performed. It led to conclude that the data were not sufficient for obtaining an optimized set of parameters and modeling René 80 behaviour.

Following, an analysis of the experimental tensile data base.

As seen, at the same temperature two tests are available for each strain-rate. It was verified that some tests performed at the same conditions (temperature and strain-rate), show a different behavior and in particular Young modulus is different (Figure 4.52).

Figure 4.52- Comparison between two tensile tests at the same temperature and strain rate

As well as, some tests performed at the same temperature and at different strain rate ( $v = 10^{-2} \text{ s}^{-1}$  and  $v = 10^{-4} \text{ s}^{-1}$ ) show different Young modulus (Figure 4.53):

Figure 4.53- Comparison between two tensile tests at the same temperature and different strain rate

In these cases, a further test for each condition (to have a statistically sufficient data base) would allow validating each test.

Besides, a further anomaly has been verified in tensile data base at  $T=900^{\circ}\text{C}$ : the two tests performed respectively at strain rates:  $v = 10^{-2} \text{ s}^{-1}$  and  $v= 10^{-4} \text{ s}^{-1}$  show a yield stress of different order of magnitude. In particular, the test at  $v = 10^{-2} \text{ s}^{-1}$  shows a yield stress twice higher of the one at  $v= 10^{-4} \text{ s}^{-1}$  (Figure 4.54).

It is important to highlight that the sensitivity to strain-rate is correct, but the difference have to be of the order of magnitude  $10 \div 20 \text{ MPa}$ .

Figure 4.54- Comparison between tensile tests at  $T=900^{\circ}\text{C}$  and different strain rates

Moreover, tensile tests are not according with other experimental data. The comparison between the tensile tests and the first cycle of LCF tests performed in the same condition shows a different behaviour.

The highlighted problems have made tensile tests unreliable in the process of Renè 80 characterization. This has limited the correct identification of Young modulus, R0 and k parameters.

Following fatigue tests analysis.

By observing the position of stabilized cyclic curve compared to the monotonic curve, it is possible to determine if material behaviour is hardened or softened under a cyclic load and high temperatures. In particular, when the stabilized cyclic curve is upper than monotonic one, material shows hardening behaviour, on the contrary, material shows softening behaviour.

The first step was then to calculate the stabilized cyclic curve by interpolating the peaks of stabilized hysteresis loops through Ramberg-Osgood law and verify material behaviour.

On the base of available experimental data, the following results were obtained at T=400°C, 800°C, 900°C:

Figure 4.55- Comparison between tensile tests and Ramberg-Osgood curve at T=400°C

Figure 4.56- Comparison between tensile tests and Ramberg-Osgood curve at  $T=800^\circ\text{C}$

Figure 4.57- Comparison between tensile tests and Ramberg-Osgood curve at  $T = 900^\circ\text{C}$

By observing Figure 4.55, Figure 4.56, Figure 4.57, the material shows hardening behaviour at  $T=400^\circ\text{C}$  and softening behaviour at  $T=800$  and  $900^\circ\text{C}$ . This is confirmed by the comparison between the first cycle and stabilized one of experimental LCF tests at  $T=400^\circ\text{C}$  and  $900^\circ\text{C}$  (Figure 4.58, Figure 4.60), differently at  $T=800^\circ\text{C}$  (Figure 4.59).

Figure 4.58- LCF test at T=400°C - First cyclic and stabilized cycle

Figure 4.59- LCF test at T=800°C - First cyclic and stabilized cycle

Figure 4.60- LCF test at T=900°C - First cyclic and stabilized cycle

This involves uncertainty in the LCF data base at T=800°C and consequently in the phase of modelling material cyclic behaviour at that temperature.

Besides, some of LCF tests show an amplitude of hysteresis loop too small (Figure 4.61), this implicates that material worked primarily in elastic field during those tests. For this reason, only the LCF tests with significant loop amplitude have been considered in the process, in way to determine hardening coefficients of material model.

This has implicated a decrease in the number of available tests.

Figure 4.61- LCF test at T=400°C and  $\Delta\epsilon_{tot} \% = 0.56$  - First cyclic and stabilized cycle

Figure 4.62- LCF test at  $T=800^{\circ}\text{C}$  and  $\Delta\epsilon_{\text{tot}}\% = 0.57$  - First cyclic and stabilized cycle

Moreover, further anomaly was found in LCF data base: some tests show values of Young modulus too scattered at the same temperature.

Figure 4.63- LCF tests – Young modulus versus Temperature

This, probably, is due to a non-homogeneous structure of material with the presence of grains of big size and macroscopic area of dendritic solidification. This has affected the process of material characterization, since the model is very sensitive to the Young modulus variations, as described following.

The comparison between the first cycle of the experimental LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\epsilon\% = 0.75$  and the simulation of the same cycle in Z-Sim is shown:

Figure 4.64- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\epsilon_{\text{tot}}\% = 0.75$  - First cyclic –simulated and experimental

It is possible to observe that the results obtained by the simulation (red data) are not in agreement with experimental test (black data). To evaluate how Young modulus parameter has influenced model material response, the same test has been simulated implementing the same material model and varying only the value of Young modulus parameter. In particular, it was replaced by the value provided by experimental data (for that LCF test). Following it is shown the comparison between simulated test and experimental one.

Figure 4.65- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\epsilon_{\text{tot}}\% = 0.75$  - First cyclic –simulated and experimental

The Figure 4.64 and Figure 4.65 show how the correct determination of Young modulus affects material model response.

The scattered values of Young modulus provided by experimental LCF tests and the uncertainties previously highlighted in experimental tensile tests represent significant limits in the process of material characterization.

Uncertainty was also verified in the determination of stabilized material behaviour. As seen, material behaviour under cyclic loads is characterized by a first transitory phase, during which material response goes progressively to stabilize. After this phase, the hysteresis cycles are overlapped. In order to model the material stabilization, for each test it is necessary to determine after how many cycles, material shows a stabilized behaviour. The stabilized cycle can be determined by maximum stress versus number of cycles for each test. In particular, when stress remains constant, this means that material is stabilized.

By observing experimental data, it has been often difficult to identify clearly the stabilized cycle for someone tests (for example see Figure 4.66):

Figure 4.66- Maximum stress versus number of cycles to failure - LCF test at  $T = 400^{\circ}\text{C}$

However, conventionally, it is assumed that the stabilized cycle is  $N = N_f/2$ , where  $N_f$  is the number of cycles to failure.

At the end, an analysis of relaxation tests has been performed. As previously described, a LCF step test is performed loading the specimen with  $N$  cycles of increasing controlled-strain at two different strain rates. After the last cycle, the load is held constant in time, in way to relax material.

Two LCF step tests were performed for each temperature.

By observing experimental data, Figure 4.67, the results of the two tests (at same temperature and same test conditions) are different at  $T=800^{\circ}\text{C}$ .

This represents a further uncertainty introduced in the process of material characterization, in particular for determining the coefficients  $M$  and  $m$ , which describe material recovery, and creep coefficients.

Figure 4.67- Stress relaxation tests at  $T = 800^{\circ}\text{C}$

#### 4.5.3 *Non uniqueness of parameters set*

Herein, it will be highlighted the main limits in using an automatic procedure of material characterization, when dealing with models that possess a very large number of constants that:

- are often lacking in their direct physical interpretation
- may have vastly different magnitudes
- are highly interactive with each other

Following the results of the simulation of the LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\varepsilon \text{ \%} = 1.19$ , performed with two different sets of coefficients: a set in which the parameters are in agreement with their physical meaning and a set obtained by the automatic procedure, in which the parameters are not in agreement with the physics.

The first set of parameters has been determined through the following steps:

- Young modulus is obtained by experimental test.
- $R_0$  is obtained from tensile test. It is the first point that gives the transition between the linear and nonlinear part of the curve.
- $Q$  is the amount of hardening obtained from difference between maximum values of stress in the stabilized cycle and in the first cycle.
- $b$  is the saturation rate of isotropic hardening. If the saturation of material is very slow (large number of cycles are necessary to go from first cycle to stabilized one), the parameter  $b$  can be taken to a small value (5 or 6), (see, Z-Mat handbook). On the contrary, if the stabilization is very quick,  $b$  can be taken equal to a value between 10-20.
- $C/D$  is the asymptotic value of kinematic hardening.

The simulation of LCF test has provided the following result, compared with experimental curve (in Figure 4.68, black data is the experimental curve, red data is the simulation):

Figure 4.68- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\varepsilon \text{ \%} = 1.19$  - Comparison between simulated and experimental test

The comparison shows a good agreement between material response and experimental data.

The second set of parameters was determined by the automatic procedure of identification, through simulations and optimizations performed with Z-Sim and Z-Opt modules. The simulation of the same LCF test provided the following result:

Figure 4.69- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\varepsilon \text{ \%} = 1.19$  - Comparison between simulated and experimental test

Again, the comparison shows a good agreement between material response and experimental data, even if, in this case, some parameters are lacking in their direct physical interpretation and have different order of magnitude (compared to the previous set).

In fact, passing from the first to the second set, the initial yield stress, in the model  $R_0$  coefficient, dropped from  $R_0 = 400$  to  $R_0 = 101$ , while the asymptotic value of kinematic hardening  $C/D$  increased by  $C/D = 140$  to  $C/D = 440$ .

The automatic procedure is based on a mathematical optimization and not always, the results are in agreement with the physics.

It is still possible to observe by the comparison between experimental curve (black data) and simulation (red data) in Figure 4.69, that even if the model shows a good predictive capability, it is not able to model correctly the yield stress.

Moreover, this result shows that the set of parameter obtained through the optimization procedure may not be unique.

The reason is that the optimization code works for obtaining the "best fit" between the curves. When the number of parameters is very high, this kind of optimization gives in output a result that may be correct by a mathematical point of view, but far from the real physical meaning of coefficients.

In this case, only a good experimental database with a consistent number of tests may limit the uncertainties.

To design an experimental database that respects these conditions is the real issue for a correct characterization of material.

#### ***4.5.4 Sensitivity of the model to the single parameters ( $E$ , $R_0$ )***

Here, it has been analysed which parameters influence mainly the material model response.

It has already shown that material model is very sensitive to Young Modulus parameter.

A little variation in Young modulus can change significantly the correspondence between model response and experimental data.

Another parameter that affects significantly the model response is  $R_0$ . Then, see how model response changes varying only  $R_0$  parameter.

Following, the simulation of a LCF test (total strain range  $\Delta\epsilon = 1.19\%$ ,  $T=400^\circ$ ):

Figure 4.70- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\epsilon \% = 1.19$  - Comparison between simulated and experimental test

Changing in the model only  $R_0$  parameter (in particular, being the initial yield stress, its real value was chosen) the result was:

Figure 4.71- LCF test at  $T= 400^{\circ}\text{C}$  and  $\Delta\epsilon \% = 1.19$  - Comparison between simulated and experimental test, changing  $R_0$

As previously observed, this anomalous response of the model depends by the optimization process, since it performs a best fit between experimental data and simulated curve (the process is an iterative loop for minimizing the error). Again, it has been shown that the final result often give parameters that are missing in their real physical meaning.

Besides, the sensitivity of the model response to the coefficient  $R_0$  has been here highlighted.

An error in its evaluation involves a significant error in the predictive response of material behaviour.

#### 4.5.5 Differences between a model with one kinematic hardening mechanism and a model with two kinematic hardening mechanisms

Following, it will be presented the comparison between the response of a model with one kinematic variable and a model with two kinematic variables. The complexity of a material model and of its characterization depends above all by the number of its variables. However, it is often necessary to increase the number of coefficients for obtaining models with a wide range of validity.

Introducing in the model a multiple kinematic hardening mechanism depends by the strain range. When the strain range is wide, one kinematic variable is not sufficient to describe material cyclic behaviour.

The model predicts a saturation of kinematic hardening under increasing strain, the speed of the saturation being fixed by the coefficient D. (Lamitre and Chaboche, 1990)

If it is chosen to represent small strains ( $< 0.5\%$  for example) correctly, the hardening effects are not well represented above  $1\%$  (at least in the stabilized regime)

Following in fact it is presented the results of three LCF tests at  $T=400^{\circ}\text{C}$  and strain range respectively:

$$\Delta\varepsilon\% = 0.746; \quad \Delta\varepsilon\% = 0.872; \quad \Delta\varepsilon\% = 1.189;$$

for which, it has been implemented the same model with one kinematic hardening variable.

In the Figure 4.72, it is shown the comparison between the experimental and simulated tests at strain range:  $\Delta\varepsilon\% = 0.746$ . It is evident that the model is able to capture the experimental data.

Figure 4.72- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\varepsilon\% = 0.746$  - Comparison between simulated and experimental test

See now if the same model is able to reproduce material behaviour for higher strain range.

Following (Figure 4.73) the comparison between the experimental and simulated tests at strain range:  $\Delta\varepsilon\% = 0.872$

Figure 4.73- LCF test at  $T = 400^{\circ}\text{C}$  and  $\Delta\epsilon \% = 0.872$  - Comparison between simulated and experimental test

It is already evident how at the increasing of the strain range, the model is anymore able to describe material behaviour.

Again, performing a LCF test in which the strain range is:  $\Delta\epsilon \% = 1.189$ , the comparison between experimental data and simulated one shows a bad predictive capability of the model (Figure 4.74)

Figure 4.74- LCF test at  $T = 400^{\circ}\text{C}$  and  $\Delta\epsilon \% = 1.189$  - Comparison between simulated and experimental test

The same comparison, shown in Figure 4.74, was repeated and the result is shown in Figure 4.75. In this case, the test was simulated adding to the material model a second kinematic hardening mechanism. The first kinematic variable saturates quickly and models accurately the linear behaviour. The second variable works for higher strains and models accurately the transition and the non-linear behaviour. By the comparison with the experimental curve, it is evident how increasing the number of parameters has allowed to obtain a better model response.

Figure 4.75- LCF test at  $T=400^{\circ}\text{C}$  and  $\Delta\varepsilon \% = 1.189$  - Comparison between simulated and experimental test

The introduction of the additional coefficients allows the refinement of the modelling as shown in the Figure 4.75. With a single kinematic variable, the calculations were very wrong for the test with the higher strain range.

#### 4.6 Design of experiments

At the previous section, it has been shown that a model have to possess a general character for becoming a law, so that while identified only by a restricted number of experiments, it is representative of other types of experiments with a predictive capability. The totality of the situations verified by a model is its field of validity. This characterizes the goodness of the model and is expressed qualitatively by the set of all possible variation histories of the variables and quantitatively by the range of the variations within which the model agrees with the physics.

As seen, the number of coefficients represents the price to pay, since the difficulties of identification essentially lie in this number. It may be easy to identify say two coefficients by “a hand” procedure, but the identification of say five coefficients in a model will involve considerable numerical work. For this reason, it is necessary to turn to the computer-aided identification. Therefore, to evaluate a model it is necessary to examine the relation quality/price=domain of validity/number of coefficients clearly

As shown by a careful analysis of the experimental data described in the previous section, a given model cannot be identified correctly unless a sufficient number of test results are available, which embrace a significant range of variation of each parameter. Otherwise, we run the risk of not determining one or more coefficients well enough.

Moreover, it has been shown that the main difficulties associated with the use of complex constitutive equations to predict the behaviour of high temperature components are the number of parameters and quality of performed experiments. It has been verified how the last aspect has affected the characterization process leading to a significant reduction of utilizable experimental tests and for each type of test it has been highlighted the main critic aspects to be avoided (scattered data, uncertainties). Further, a not sufficient data base has involved a reduction in the model parameters and, consequently, the resulting model may not have a general character and not describe correctly material behaviour.

For this reason, it wants to provide guidelines for designing experiments able to identify the optimal set of parameters.

It is necessary to fit the material properties and behaviour to be investigated. The developed work has led to identify the constitutive equations able to predict the behaviour of high temperature components under cyclic loads.

It has been shown that two dissipation potentials, which describe the evolution mechanisms of inelastic deformation associated respectively to slow and high strain rates, are necessary to accurately capture the loading-rate dependency of material behaviour. Besides, it has been show how in the case of cyclic loading, a multiple hardening mechanism does a significantly better job of representing the real material behaviour over the entire strain range. In order to describe the evolution of the hardening under cyclic loads, the combination of isotropic and kinematic models has been implemented, in this way it has been modelled the size variation of elastic domain and of its translation. The viscoplasticity with isotropic and kinematic hardening combine plasticity and creep and allow taking into account of the rate dependence.

The identification of the constitutive laws, able to describe the material behaviour, provides a reference for a correct designing of experimental tests.

The data have to be quite extensive, a sufficient number of repetitions for each test have to be provided, as well as a sufficient variety of experimental data in order to obtain a model with a general character and a wide field of validity. Besides, two different groups of tests have to be designed: for characterization and validation processes respectively. In particular, tests within the reversible domain (i.e., creep with recovery upon complete unloading, and relaxation) and experiments conducted within the irreversible domain (i.e., relaxation, conventional creep, multi-step creep, tensile curves at different total strain rates) have to be used for characterization; while multiple-step relaxation, cyclic and plasticity/creep interaction tests have to be reserved for validating the predictive behaviour of the model.

It is important to realize from the outset, that the resulting set of material parameters is non-unique (due to the non-linear nature of the problem), however if a sufficient amount of “data content” is available, then it believes that the final obtained parameters are relatively independent of the initial guess and bounds provided.

It is suggested to separate the characterization process of the elasto-visco-plastic model in more stages:

- 1) Determine the viscous flow and initial yield stress ( $n$ ,  $k$ ,  $R_0$ ) using the tensile curves at different total strain rates. This kind of tests allows calibrating the viscous effects and the dependence of material behaviour by loading - rate.

- 2) Determine the hardening parameters ( $C$ ,  $D$ ,  $Q$ ,  $b$ ) by the LCF tests and LCF-step tests. The implementation of the non-linear kinematic hardening model allows taking into account of the effects due to the deformation history by determining the increment of accumulated plastic strain. This allow considering a hardening varying with continuity for describing the non-linearity of the process of cyclic plastic deformation.

- 3) Determine the thermal recovery parameters ( $m$ ,  $M$ ) given the relaxation, conventional creep and multi-step creep tests while keeping the flow and hardening parameter estimates from step 1 and 2 fixed. These kinds of tests allow describing the time-dependent (short-term and long-term) material behaviour.

- 4) Fit all tests at one time to obtain final parameter estimates, this is accomplished by allowing all visco-plastic parameters to be active (using the material parameters found in steps 1, 2 and 3 as initial starting values) but with tight upper and lower bounds around each parameter.

This approach allows reducing the convergence problems of solution described previously.

In the designing of experimental tests, it is important to consider that if one focused on only one type of loading condition, superior correlations could of course be achieved for that class of loading. However, predictions of other classes of loading may severely suffer. For example, during a separate characterization process involving only tensile tests, excellent correlation was obtained, but at the expense of poor creep and relaxation behaviour for a given set of material parameters. Conversely, when the model was calibrated for creep responses, poorer tensile and relaxation behaviours were similarly predicted. Thus when judging the “goodness” of a given model, one must keep in mind the appropriate required “data content” for accurately capturing the full range of material behaviour of interest.

For an identical material and model, it may be necessary to define several sets of coefficients, each better suited to a domain of variation or to a load type, for example, rapid transient loads, short-term loads, long-term loads and stationary loads.

Another important aspect is the scattering of experimental results. This can be due to:

- The nature of the phenomenon, inhomogeneities, random growth processes, and load uncertainty.
- The inherent scattering in each sample arising from the production or casting process and also from the heat treatment, and so on.

Usually, scattering is of the order of 1-5% for elastic strains, 10-50% for plastic or viscoplastic strains, 50-100% (factor of 2) of the number of cycles for low cycle fatigue crack initiation or growth, and 1000% (factor of 10) for fatigue failure in the high cycle regime.

These orders of magnitude of scattering indicate at once the pronounced influence of nonlinearities of the phenomena. The simplest and most efficient way of including this scattering in a model consists in giving a statistical definition to the multiplying coefficients present in the model. (Lemaitre and Chaboche, 1990)

Knowing a mathematical model by its analytical expression, and obtaining a set of experimental results in which all the variables of the model have been activated, one is in a position to calculate the unknown coefficients that give the best representation of the experimental results.

#### **4.6.1 Check by phenomenological aspect**

At the end of the identification process of material model parameters, it is necessary to make a check through the evaluation of phenomenological aspects derived experimentally.

As described in the previous section, useful information, to perform a procedure of material characterization, are provided by the identification of the stabilized cyclic hardening curve, i.e., the peaks of stabilized cycles ( $\sigma_{\max}$ ,  $\varepsilon_{p,\max}$ ) in the ( $\sigma$ ,  $\varepsilon_p$ ) graph.

Cyclic hardening curve can be located above (cyclic hardening) or below (cyclic softening) the monotonic hardening curve. The identification of its expression in terms of stress and strain variables presents a problem linked to the history of deformation. As a matter of fact, the curve may not be exactly the same if it is obtained by continuous variation, as it would be if it is obtained by imposing finite increments in stress or strain ranges, or if one or several specimens are used.

To identify a simple relation between the stress and strain ranges and to verify the uniqueness of the cyclic hardening curve, several methods can be used.

It is recommended of performing tests in which the strains are varied stepwise, first increasing and then decreasing. After stabilization of hardening at the lowest level, a resumption of hardening at a

higher level is an identification of the dependence between the cyclic hardening and the strain amplitude. During decreasing levels, the memory effect of the previous load is clearly established by comparison of loops obtained for the same strain level.

This type of test, where the strain is varied in steps, generally provides sufficiently detailed indications of the uniqueness of this curve with only one specimen. On the other hand, when the uniqueness is not evident, the test may be used to define a more complex model which takes into account the influence of the strain path. Five increasing steps and three decreasing steps in every twenty cycles are usually sufficient. (Lemaitre and Chaboche, 1990)

When the cyclic hardening curve is determined, some important information can be obtained by it. It is possible to check material behavior (hardening or softening) under cyclic load and for each temperature at which the test is performed.

Besides, it is possible to evaluate the order of magnitude of  $R_0$  parameter by the stabilized cyclic curve.  $R_0$  can be assumed as the value of the stress in correspondence of the smaller amplitude of plastic strain.

Further, it is possible to evaluate the order of magnitude of  $Q$ . It may be obtained by the difference between the maximum stress (that is the asymptotic stress value) and the  $R_0$  value just calculated.

For checking the consistency of the model for the whole temperature range, it is possible to calculate the conventional values of tension (for example  $R_m$  and  $R_{0.2}$ ) through the following laws (Lemaitre and Chaboche, 1990):

- Modeling of  $R_m$  (maximum stress), assuming  $\dot{\epsilon}^p \approx \dot{\epsilon}$

$$R_m = R_0 + Q + \frac{C}{D} + k \cdot (\dot{\epsilon}^p)^{\frac{1}{n}} \quad (4.23)$$

- Modeling of  $R_{0.2}$  (the conventional elastic limit: it is the stress that corresponds to the occurrence of permanent strain equal to 0.2 %), assuming  $\dot{\epsilon}^p \approx \dot{\epsilon}$

$$R_{0.2} = R_0 + Q \cdot (1 - \exp(-0.002 \cdot b)) + \frac{C}{D} \cdot (1 - \exp(-0.002 \cdot D)) + k \cdot (\dot{\epsilon}^p)^{\frac{1}{n}} \quad (4.24)$$

- Modeling of the cyclic hardening curve (amplitude of stress versus amplitude of plastic strain) (assuming  $\dot{\epsilon}^p \approx \dot{\epsilon}$ )

$$\frac{\Delta \sigma}{2} = R_0 + Q + \frac{C}{D} \cdot \tanh(D \cdot \frac{\Delta \epsilon^p}{2}) + k \cdot (\dot{\epsilon}^p)^{\frac{1}{n}} \quad (4.25)$$

- Secondary creep rate:

$$\dot{\epsilon}^p = \left\langle \frac{\sigma - \frac{C}{D} - R - R_0}{k} \right\rangle^n \quad (4.26)$$

- Asymptotic stress in relaxation:

$$\sigma_{\infty} = R_0 + Q + \frac{C}{D} \quad (4.27)$$

In this way it is possible to verify the goodness of the coefficients set by the phenomenological aspects determined experimentally.

As a matter of fact, the known parameters ( $R_m, R_{0.2}, \dot{\epsilon}^p, \sigma_{\infty}$ , cyclic hardening curve) obtained in output from experimental tests, may be calculated according the previous equations (that involve the model coefficients), and by the comparison between the order of magnitude of the values such calculated and their real values, it is possible to verify preliminarily the coefficients set.

At the end, the order of magnitude of the coefficient k may be also verified by the Norton law:

$$\sigma_v = k \cdot (\dot{\epsilon})^{\frac{1}{n}} \quad (4.28)$$

In which  $\sigma_v$  is viscous stress. The difference between the tensile tests at different strain rates allows evaluating the amplitude of the viscous stress and by the previous equation, it is possible to calculate k value for one strain rate (supposing a fixed value for n).

## **5 Application of elasto-visco-plastic material models to cases of industrial interest.**

### **5.1 Introduction**

In the present chapter, it will be described in which way a procedure for FEM structural analysis, implementing elasto-visco-plastic material models, has been developed and validate, in order to determine stress-strain state of components under cyclic loads and high temperatures.

Elasto-visco-plastic analysis allows evaluating the real material behaviour and structure life in a more accurate way, taking into account the nonlinear interaction between the two mechanisms of damage: fatigue and creep.

In particular, starting from an elasto-visco-plastic material model, already characterized and validated, it has been possible to test its effectiveness by performing comparison analysis with known models in linear-elastic and elasto-plastic fields.

Besides, by the implementation of known damage models a procedure for calculating structure life taking into account of nonlinear interaction between creep and fatigue has been developed and validate

The methodology of analysis has been applied to a case of industrial interest. An elasto-visco-plastic analysis has been performed on a combustion chamber of aeronautical engine and structure life has been evaluated.

Finally, the response of material model, characterized at the previous chapter, has been evaluated. The model has been implemented to perform a preliminary elasto-visco-plastic analysis on a portion of a turbine blade.

Starting from the obtained results, it will be possible to plan a new campaign of experimental tests for a complete material characterization.

The introduction of such complex models will allow an improvement of turbine blades designing. In fact, the capability of reproducing the real material behaviour and predicting the component life in a more accurate way, allow reducing the traditional factors of safety that are overly conservative and preventing from achieving the optimal efficiency in structural designing process.

### **5.2 Procedure of elasto-visco-plastic analysis**

The objective of this section is to develop a procedure of structural analysis that, through the comparison with procedures of tested validity, allows a correct and safe implementation of elasto-visco-plastic material models.

The comparison between structural analysis of a component modeled to finite elements using ANSYS standard material models and user-defined material models implemented in ANSYS through the interface with Z-Mat code, has been developed through the following phases:

- Choice of a test case
- Linear elastic analysis
- Elasto-plastic analysis

- Elasto-visco-plastic analysis

The activities that will be described in the present section have been developed in collaboration with AVIO-Propulsione Aerospaziale.

Elasto-Visco-Plastic analysis can be performed adopting Z-Ansys module implemented in Z-Mat software. It is sufficient to generate a subroutine that links ANSYS to Z-Mat. More in detail will be sufficient to put in a folder

- The file (i.e. *Jobname.inp*) containing FE model, loads, boundary conditions and solution parameters.
- The file containing all the necessary material parameters (classes, modules and coefficients).

It is important to notice that the material filename must be always defined as *10x.txt* where *x* is a number varying from 1 to 9. If there will be different materials constituting the structural component, it will be necessary to insert different files for each material.

The first step is to choose the ANSYS elements that are defined as *user-mat*; in fact, for these kinds of elements will be possible to define an external material model and behaviour.

The file *jobname.inp* is obtained by issuing the ANSYS command CDWRITE after than the model has been completely meshed, all the boundary conditions and forces have been applied, and a dummy material model has been assigned.

In the /PREP7 section, after the ANTYPE command, which selects the type of analysis, must be added the lines recalling the external material model. Using the TB Ansys command with the USER and STATE options:

```
TB, USER, 1, 0, 0
TB, STATE, , 40
```

These lines recall the material file defined as *101.txt*

At the end of all these activities, the /SOLU Ansys command must be issued. In this step must be defined the type of analysis and its options, loads will be applied, together with load-step options.

Through the EQSLV is chosen the type of analysis. The preferred one must be the PCG (Pre-conditioned Conjugate Gradient iterative equation solver), because is the one that best fits non-linear analyses.

Issuing the command NROPT,FULL,,OFF “complete” Newton-Raphson method will be selected, in this way, the stiffness matrix of the element is calculated at each equilibrium iteration. At this command, has been associated the option *adaptive descent off* that uses “tangent stiffness matrix” every equilibrium iteration.

The following step is to proceed to loads applications and load-step length definition. Of course, loadstep and substep definition can be set to variable dimension in each cycle.

The allowable options to perform a non linear analysis are the following:

- TIME is a parameter that grows monotonically, never equal to zero. With this command ANSYS identifies each load step and substeps.
- NSUBST defines number of substeps in which each load step is divided. This option allows establishing initial value and minimum and maximum step amplitude.
- AUTOTS is a command that allow software to decide how many time steps are foreseen in each load step. At the end of each time step, the amplitude of the following one is predicted based on the number of equilibrium iterations spent in the previous loadstep. (The more is the number of equilibrium iterations, the less is the amplitude of the time step)

Using the command AUTOTS, ON, an automatic restart technique is activated if convergence within the specified loadstep parameters is not reached. The program itself is able to set back to the last converged loadstep, half part the un-converged loadstep and re-run the analysis automatically. This process is repeated until convergence or the minimum timestep lengths are reached. (The minimum timestep length is equal to the maximum number of allowed substeps issued through the NSUBST command)

The solver will continue to use equilibrium iterations, until the user defined convergence criteria, issued through the CNVTOL command, will not be satisfied. (Or, on the contrary, until the maximum equilibrium iterations number, issued through the command NEQIT, is reached)

The output control is executed through the OUTRES command. With this command is possible to establish the frequency of the solution steps that have to be saved in the output file.rst. The solutions calculations start executing SOLVE command. To close the solution it is necessary to issue the FINISH command.

### **5.2.1 Test case**

The test case utilized in this section is a simulacrum of aeronautical engine combustor (project CPLife - Figure 5.1) realized with Haynes y, a Nichel base super-alloy (for reserved of industrial data, it is not possible to indicate the complete material name).

Figure 5.1- Simulacrum of CPLife combustor

In Figure 5.2 and Figure 5.3, it is shown respectively the geometry of simulacrum and a particular of the ring holding. The simulacrum, in fact, is divided in two parts: liner and ring holding.

Figure 5.2- Simulacrum geometry

Figure 5.3- Ring holding

The FEM model of simulacrum has been realized (Figure 5.4). The element type is SOLID186 and the model details are summarized in Table 5.1.

	<b>NODES</b>	<b>ELEMENTS</b>
<b>TOTAL MODEL</b>	56005	10061
<b>LINER</b>	47829	8736
<b>RING HOLDING</b>	8176	1325

Table 5.1 – FEM model details

Figure 5.4- FEM model

The mechanical loads are the difference of pressure between internal and external face of the liner  $\Delta p = 0.018$  MPa and the closing pressure on the ring  $p = 0.0509$  MPa (Figure 5.5).

Figure 5.5- Simulacrum FEM model - Mechanical loads

The constraints are applied on nodes located in front section of liner to block axial and tangential displacements (Figure 5.6).

Figure 5.6- Simulacrum FEM model - Constraints

The thermal maps applied to the model were determined through experimental measurements. In Figure 5.7, it is shown the thermal loads in the maximum stabilized condition in service.

Figure 5.7- Simulacrum FEM model – Thermal loads (plane development)

Loads, constraints and material data were obtained by CPLife documentation, made available by AVIO.

### 5.2.2 Linear-elastic analysis

By the available material experimental data (CPLife documentation) and by the methodology of material characterization developed and described at the previous chapter, a linear-elastic material model has been developed and implemented in ANSYS code through the software Z-Mat. In this way, a linear analysis has been performed on simulacrum.

To verify the reliability of the developed material model and its correct implementation in ANSYS, an analogous analysis has been performed utilizing the linear-elastic model of FEM code.

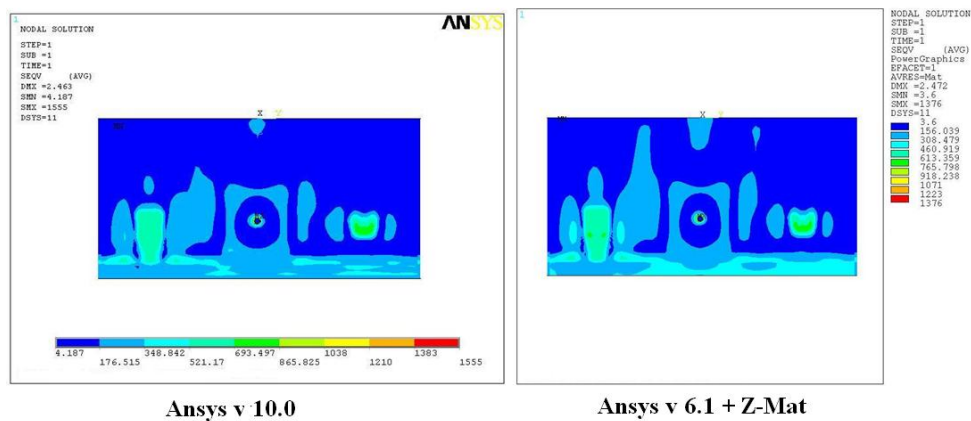

Figure 5.8- Linear-elastic analysis - Von Mises stress – plane development

In Figure 5.8 it is shown the comparison between the results of the two analysis. In particular, on the left the Von Mises stress (plane development) obtained from the analysis performed utilizing the ANSYS (v 10.0) linear-elastic material model. On the right, the Von Mises stress (plane development) obtained from the analysis performed implementing the external defined material in ANSYS (v 6.1).

By the comparison, the stress analysis has provided values with a gap not higher than 1.2 %. With the exception of the most critical zone of the dilution hole where, in correspondence of the peaks, the gap does not exceed the 11.1% (Figure 5.9 and Figure 5.10).

For these reasons, the elastic model has been considered reliable and its implementation in ANSYS correct.

Figure 5.9- Ansys linear-elastic analysis - Von Mises stress – Dilution hole

Figure 5.10- Ansys + Z-Mat linear-elastic analysis - Von Mises stress – Dilution hole

### 5.2.3 Elasto-plastic analysis

By the available experimental data (CPLife documentation) and by the methodology of material characterization developed and described at the previous chapter, two elasto-plastic material models have been developed and implemented in ANSYS code through the software Z-Mat. In particular, among the models that describe the material elasto-plastic behaviour, a model with an isotropic hardening mechanism and a model with a kinematic hardening mechanism have been chosen. Coherently with the available experimental data, the model coefficients were calculated for each temperature through the process of simulation and optimization. In this case the coefficients involved in the two elasto-plastic models are:  $R_0$ ,  $Q$  and  $b$  for the isotropic hardening rule and  $R_0$ ,  $C$  and  $D$  for kinematic hardening rule.

In this way, two nonlinear analysis were performed on simulacrum, considering the elasto-plastic material behaviour once isotropic and then kinematic.

To verify the reliability of the developed material models and their correct implementation in ANSYS, the same experimental data were utilized for defining the elasto-plastic material models already available in ANSYS library.

In particular, the ANSYS elasto-plastic material models with isotropic and kinematic hardening are respectively: MISO (Multilinear Isotropic Hardening) and MKIN (Multilinear Kinematic Hardening). Besides, these are the material models utilized for this type of structural analysis, until now.

Multilinear Kinematic Hardening option (MKIN) uses the Besseling model, also called the sub-layer or overlay model. Heterogeneous nature of deformations causes, in microscopic scale, a network of dislocations in directions imposed by load type. In this way, hardening is not uniform in all directions (Bauschinger effect), see Figure 5.11.

Figure 5.11- Multilinear kinematic hardening rule- Bauschinger effect

In this model, the material is seen as a set of sub-layers. The plastic strains remain constant by scaling the sub-layers. Each sub-layer is characterized by a simple stress-strain curve and, by combining these curves, the multilinear response is obtained (Figure 5.12), that shows the effect of kinematic hardening.

Figure 5.12 – Multilinear kinematic response

With the command MKIN is possible to introduce the stress-strain curves for temperature dependent properties.

Figure 5.13- Multilinear kinematic hardening -curves

In Figure 5.13, an example of typical stress-strain curves for the MKIN option, where each of them is a stress-strain curve (obtained by five stress-strain values) at constant temperature.

Multilinear Isotropic Hardening option (MISO) uses Von Mises Yield criterion. Deformations cause accumulation of intermolecular dislocations. This causes material hardening, because of the dislocations obstruct motion among crystalline planes. Hardening rule is assumed uniform in all load directions (Figure 5.14).

Figure 5.14- Multilinear isotropic hardening rule

The multilinear isotropic hardening response is shown in Figure 5.15:

Figure 5.15 – Multilinear isotropic response

With the command MISO is possible to introduce the stress-strain curves for temperature dependent properties, so, for each temperature, multilinear stress-strain curves are implemented. The

MISO option can contain up to twenty different temperature curves, with up to one hundred different stress-strain points allowed per curve.

The experimental stress-strain curves implemented in ANSYS for both options MKIN and MISO are the following (defined in the temperature range of the analysis), see Figure 5.16:

Figure 5.16 – Curve MKIN – MISO for simulacrum material model definition in ANSYS

In this way, two elasto-plastic analysis analogous to the ones performed implementing external material models, have been executed.

Following, the comparisons between the analysis performed implementing external material models and ANSYS elasto-plastic models.

The first comparisons refer to the analysis performed considering elasto-plastic material behaviour with isotropic hardening.

In Figure 5.17, it is shown the comparison between the Von Mises stress calculated with ANSYS material model (MISO) (on the left) and implementing in ANSYS the Z-Mat elasto-plastic material model with isotropic hardening (on the right).

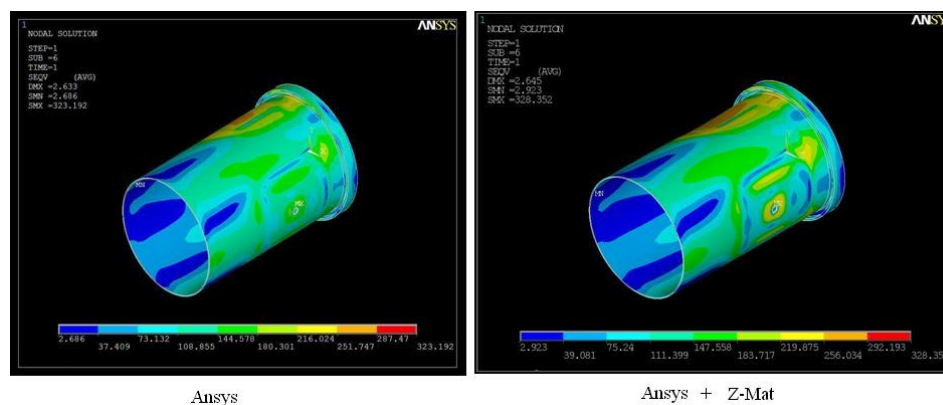

Figure 5.17 – Elasto-plastic analysis (isotropic hardening) - Von Mises stress

In Figure 5.18, it is shown the comparison between the displacements vector sum calculated with ANSYS material model (MISO) (on the left) and implementing in ANSYS the Z-Mat elasto-plastic material model with isotropic hardening (on the right).

Figure 5.18 – Elasto-plastic analysis (isotropic hardening) – Displacement vector sum

The following comparisons have been performed considering elasto-plastic material behaviour with kinematic hardening.

In Figure 5.19, it is shown the comparison between the Von Mises stress calculated with ANSYS material model (MKIN) (on the left) and implementing in ANSYS the Z-Mat elasto-plastic material model with kinematic hardening (on the right).

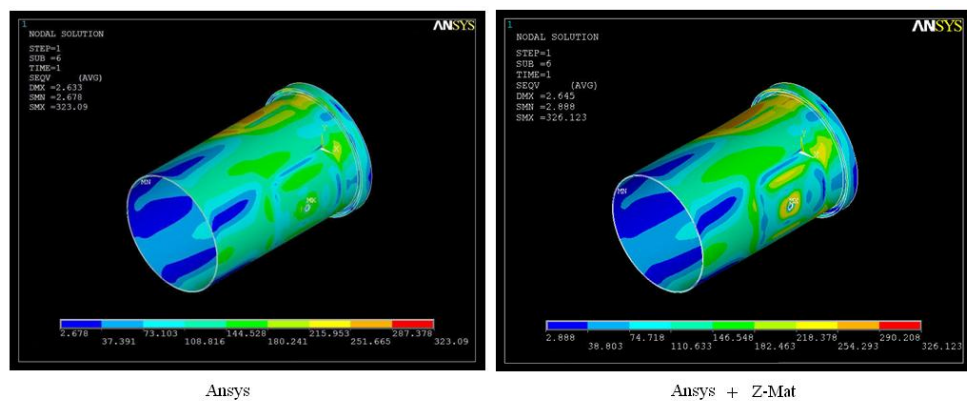

Figure 5.19 – Elasto-plastic analysis (kinematic hardening) - Von Mises stress

In Figure 5.20, it is shown the comparison between the displacement vector sum calculated with ANSYS material model (MKIN) (on the left) and implementing in ANSYS the Z-Mat elasto-plastic material model with kinematic hardening (on the right).

Figure 5.20 – Elasto-plastic analysis (kinematic hardening) – Displacement vector sum

By the comparisons between elasto-plastic analysis performed with ANSYS material models and, subsequently, implementing in ANSYS the developed external material models, it has been observed in both the hypothesis of isotropic and kinematic hardening that:

- The gap in displacement values is lower than 0.7 % in all considered conditions
- The gap in stress values is lower than 0.93 % in all considered conditions, including the most critical area of the dilution hole.

Since by the comparison, it has been found a good correspondence between the analysis results, it is possible to consider correct the developed procedure of material characterization and implementation of external material models in ANSYS.

For these reasons, the elasto-plastic models have been considered totally reliable.

#### 5.2.4 Elasto-visco-plastic analysis

In this phase, after to have obtained the results of linear-elastic and elasto-plastic analysis, an elasto-visco-plastic analysis has been performed on simulacrum and on specimens subjected to characterization tests.

In this case, it was not still available all the characterization tests necessary for the development of the Chaboche elasto-visco-plastic model of the material under examination. So, with the aim to develop and validate a methodology of structural analysis implementing elasto-visco-plastic material models, the Chaboche EVP model of the Nickel base superalloy Haynes x (with mechanical properties similar to Haynes y) already characterized was utilized.

In this way, it has been evaluated the effectiveness of the elasto-visco-plastic model compared to the results obtained by known models in linear-elastic and elasto-plastic field, previously implemented (paragraphs 5.2.2 and 5.2.3) and until now utilized for this type of analysis.

Preliminary analysis on the specimens of tensile, LCF and creep tests, were performed in order to test the model and its correct implementation in FEM code.

The EVP model of Haynes x was implemented in ANSYS code and numerical simulations of characterization tests (tensile, LCF and creep) were performed. In this case, simulations of

experimental tests were performed also by Z-Sim module of Z-Mat code, in order to compare the results for testing the material model and its correct implementation in ANSYS.

#### 5.2.4.1 Simulation of characterization tests

Among the characterization tests that were simulated, it reports the followings (Table 5.2):

Test Type	T [°C]	Strain rate [1/s]	Controlled-strain [% $L_0$ ]	Strain ratio $R_\epsilon$
LCF	20	$10^{-2} - 10^{-4}$	0.3 – 0.5 – 0.7 – 0.9	-1

Table 5.2 – LCF tests simulated

Each test has been performed applying for each level of controlled-strain, the two strain rates through the following subsequently steps:

- 100 cycles at  $\epsilon\% = 0.3$  and  $\nu = 0.01/s$ ; time of one cycle = 1.2s – total time = 120s
- 100 cycles at  $\epsilon\% = 0.3$  and  $\nu = 0.0001/s$ ; time of one cycle = 120s – total time = 12000s
- 100 cycles at  $\epsilon\% = 0.5$  and  $\nu = 0.01/s$ ; time of one cycle = 2s – total time = 200s
- 100 cycles at  $\epsilon\% = 0.5$  and  $\nu = 0.0001/s$ ; time of one cycle = 200s – total time = 20000s
- 100 cycles at  $\epsilon\% = 0.7$  and  $\nu = 0.01/s$ ; time of one cycle = 2.8s – total time = 280s
- 100 cycles at  $\epsilon\% = 0.7$  and  $\nu = 0.0001/s$ ; time of one cycle = 280s – total time = 28000s
- 100 cycles at  $\epsilon\% = 0.9$  and  $\nu = 0.01/s$ ; time of one cycle = 3.6s – total time = 360s
- 100 cycles at  $\epsilon\% = 0.9$  and  $\nu = 0.0001/s$ ; time of one cycle = 360s – total time = 36000s
- 5 hours at  $\epsilon\% = 0.9$  (Stress relaxation)

The specimen utilized for LCF tests is :

Figure 5.21 – LCF tests specimen

For the geometric symmetry of loads and constraints, only a quarter of the specimen has been modelled (Figure 5.22)

Figure 5.22 – LCF tests specimen – FEM model

The main features of the FEM model are the following:

	Element Type	Nodes	Elements
FEM Model	Plane 183	2228	685

Table 5.3 – Main features of FEM model

Since, it is not possible to perform controlled-strain tests in ANSYS, the displacement that causes the controlled-strain has been calculated and applied in nodes (in correspondence of the holding area) as shown in Figure 5.23:

Figure 5.23 – LCF tens specimen – Loads

The tests have been performed implementing the elasto-visco-plastic model of Haynes x in ANSYS.

In Figure 5.24, it is shown the stabilized cycles obtained for each load condition.

Figure 5.24 – EVP analysis - ANSYS simulation of LCF tests at  $R_\epsilon = -1$  and  $T = 20^\circ\text{C}$  (stabilized cycles)

The LCF tests, described in the Table 5.2, have been simulated through Z-Sim code applying the same conditions and the same material model, obtaining the following results:

Figure 5.25 – EVP analysis – Z-Sim simulation of LCF tests at  $R_\epsilon = -1$  and  $T = 20^\circ\text{C}$

The simulations have provided the same results. In addition, simulations of experimental tensile and creep tests have been performed both in ANSYS and Z-Sim, implementing the same material model. Again, coincident results have been obtained. In this way, it has been possible to test the elasto-visco-plastic material model and its correct implementation in ANSYS.

#### 5.2.4.2 Elasto-visco-plastic analysis on combustor simulacrum

Elasto-visco-plastic analysis has been performed on simulacrum. A typical procedure of thermomechanical stress analysis of a combustor has been applied, implementing a simpler and cyclically repeated mission.

By comparing the results with the ones obtained from previous analysis, it has been highlighted and verified the possibility to reproduce the physical phenomena, (for example: stress relaxation) that may be appreciated only through an analysis performed with a *rate dependent* material model.

In fact, the elasto-visco-plastic model does not consider the *time* variable as a simple counter, that scans the succession of load configurations, but associates to it the real physical meaning. In this way, both the loads application and material behaviour become *rate dependent*.

For this reason, the material model is able to simulate at once, material creep under (thermal and mechanical) loads for long time and the effect of “diffusion” that it causes.

The thermomechanical load cycle applied to simulacrum is shown in Figure 5.26 . The cycle phases are:

- Ignition and acceleration
- Hot hold time
- Cold hold time

Figure 5.26 – Thermomechanical load cycles applied to simulacrum

The cycle is repeated until to the stress stabilization: ten load cycles were applied.

As already introduced in detail at paragraph 5.2, in a non-linear analysis, each load condition is a load step and each load step is divided in substeps. The substeps thicken at the beginning of the variation of load condition.

Figure 5.27 – Thermomechanical load cycle applied to simulacrum – details

To perform a non-linear analysis the following options have been used:

- PCG solver
- Automatic control of time step size [SOLCONTROL,ON,ON]
- Automatic control of substeps number in each load step, through an estimate of convergence rate of previous substep [AUTOTS,ON].
- Newton-Raphson “complete” method (material stiffness matrix is calculated at each equilibrium iteration), with the *adaptive descent off* option [NROPT,FULL,,OFF]
- Convergence criterion based on force [CNVTOL,F,2000,0.001]

Following, the most significant analysis results.

In Figure 5.28, it is shown the axial stress versus axial strain in a node in correspondence of dilution hole, which is the most critical area (maximum stress). The highlighted points (A,B,C) are the time points of the load cycle. It is possible to observe the material stabilization after ten cycles of load.

In Figure 5.29 it is shown the Von Mises stress time history of the first cycle of load, calculated in the same node. The material stress relaxation, under a load constant in time, is shown. In fact, going from the time poin A to time point B of the mission, in the steady state condition, the resulting stress is not constant but it decreases.

In Figure 5.30, in order to highlight the cyclic stabilization of material, it is shown the stress time history of all cycles, calculated in the node indicated in Figure 5.28. The envelope of maximum and minimum stress has been calculated too, in way to verify the stabilization (that is shown in detail in Figure 5.31).

Figure 5.28 – Axial stress vs. axial strain on the border of the dilution hole

Figure 5.29 – Von Mises stress time history of the first cycle

Figure 5.30 – Stress time history of all cycles

Figure 5.31 – Stress time history – maximum and minimum stress envelope

In Figure 5.33, it is shown the comparison between the contour plots of Von Mises stress, calculated in the time point A (see Figure 5.32) of the first and last cycle, in order to observe the material stabilization.

Figure 5.32 – Point A of mission

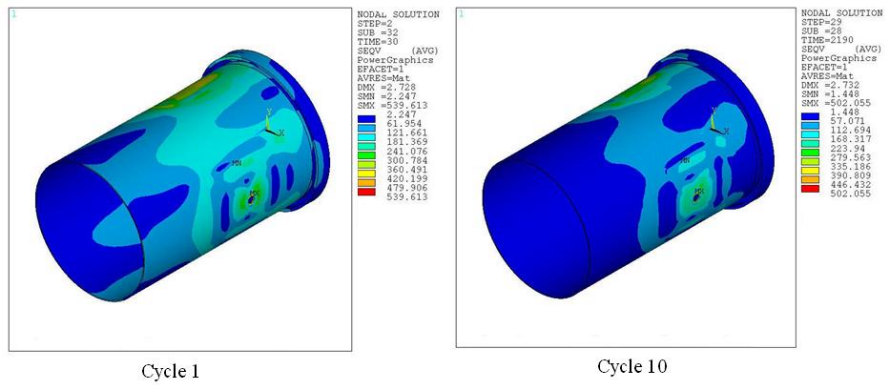

Figure 5.33 – Stabilization of Von Mises stress

The Figure 5.34 shows instead, the stress delta between a cycle and the next one, until the 10<sup>th</sup> (time point A), from which it is still possible to verify the material stabilization.

Figure 5.34- Stress delta between cycles

The following plots (Figure 5.35) show the results of the stress relaxation that the component has during its steady state condition (from time point A to point B of mission).

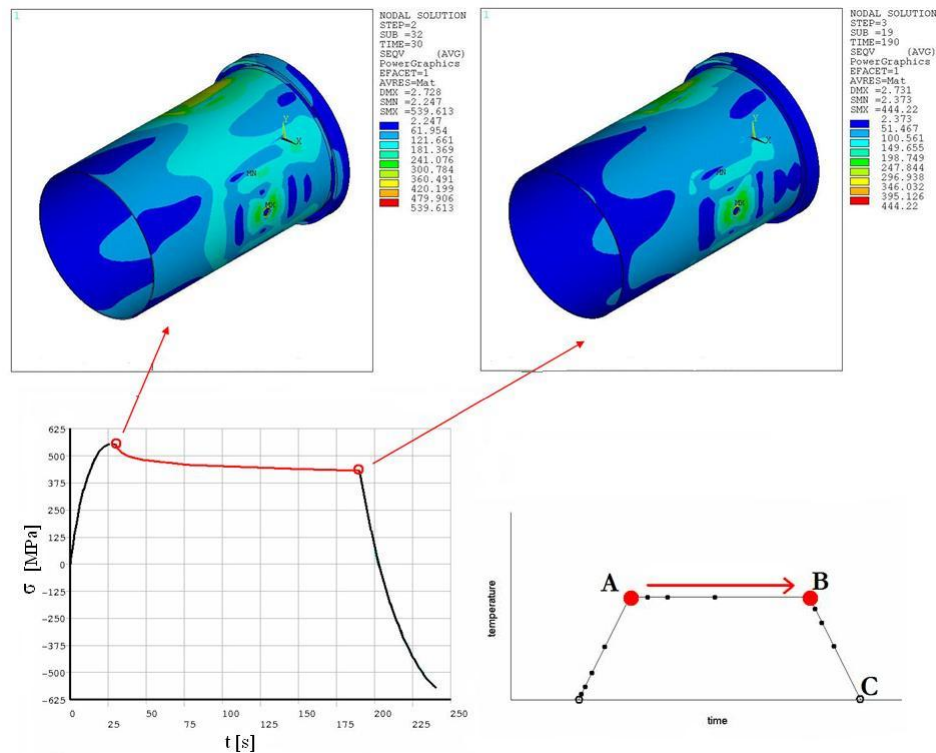

Figure 5.35- Stress relaxation during steady state condition within a cycle

The two Von Mises stress contour plots (Figure 5.35) show the same structure, in the same cycle at the end of the start up sequence and before the shut down procedure. The Von Mises stress time history of the first load cycle, calculated in a critical node (maximum stress) on the bord of dilution hole, shows the stress relaxation verified in the steady state condition.

Previous material models were not able to show stress relaxation.

In fact, elasto-plastic models always show the same stress if loads and boundary conditions remains the same. This is not the case of this time dependent material model.

In Figure 5.36, it is shown a comparison among the results of the stress analysis performed on simulacrum with the three different material behaviour models. Differently from the elasto-plastic model, the elasto-visco-plastic material model is *rate dependent*: stress depends by strain-rate and so by the rate of load application.

The elasto-visco-platic model is able to predict the real material behaviour under thermomechanical cyclic loads, it shows stress relaxation under a load constant in time and stress stabilization under a cyclic load, after some cycles (in this case after about four/five cycles).

For these reasons, the elasto-visco-plastic model allows to analyse structural components under thermomechanical loads, taking into account the non-linear interaction between fatigue and creep.

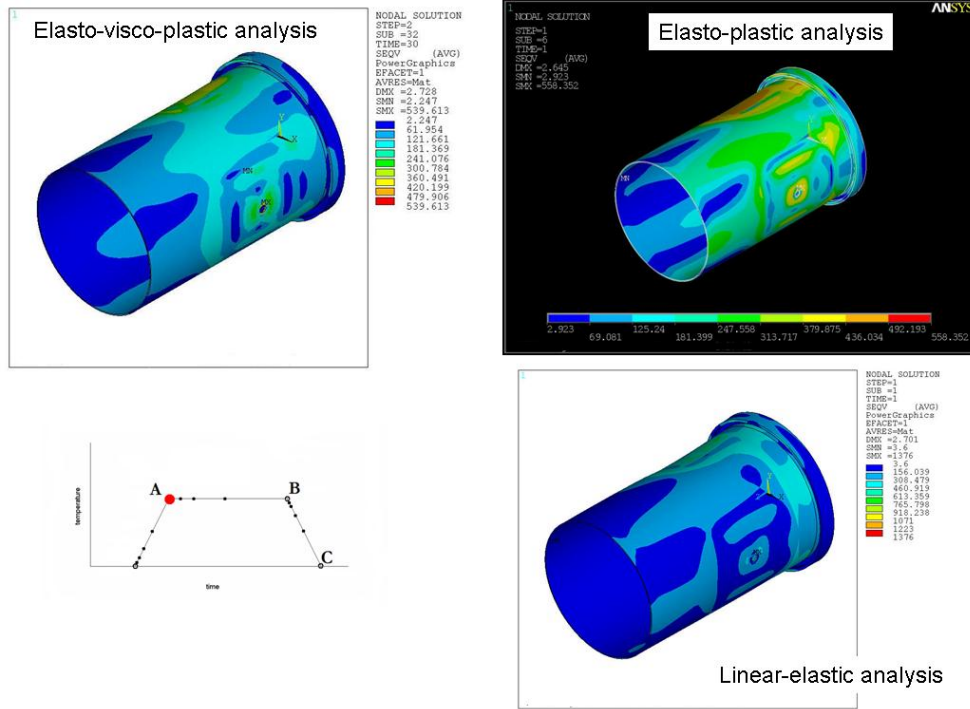

Figure 5.36- Comparison among the different material models behaviour

### 5.3 Life calculation procedure

With the aim to develop a new procedure of life calculation for structural components, considering the nonlinear interaction between creep and fatigue, the damage laws of Chaboche and Rabotnov-Kachanov implemented in Z-Post module have been chosen, and the available damage models and already characterized have been used. By the comparison between the results obtained by Z-Post and the ones obtained by the implementation of the same laws in spread sheet and FORTRAN algorithms, the procedure has been validated and make available for the application to a case of industrial interest.

#### 5.3.1 Fatigue life calculation procedure

In the first phase it has been validated the procedure of fatigue life calculation.

The model used in this work and implemented in Z-Post is the fatigue damage model developed at Onera by Chaboche (Chaboche 1974, 1986).

The number of cycles to rupture is calculated with the following relation:

$$N_F = \frac{\langle \sigma_u - \sigma_{Max} \rangle}{a(\beta + 1) \langle \sigma_{Max} - \sigma_1(\bar{\sigma}) \rangle} \left( \frac{\sigma_{Max} - \bar{\sigma}}{M(\bar{\sigma})} \right)^{-\beta} \quad (5.1)$$

Obtained through the integration of the damage growth rate law:

$$\frac{dD}{dN} = \left[ 1 - (1 - D)^{\beta+1} \right]^{\alpha(\sigma_{Max}, \bar{\sigma})} \left( \frac{\sigma_{Max} - \bar{\sigma}}{M(\bar{\sigma})} \right)^{\beta} \quad (5.2)$$

Where:

$\sigma_{Max}$  = Maximum stress of the cycle

$\bar{\sigma}$  = Average stress of the cycle

$\sigma_u$  = Ultimate tensile stress

$\beta$  = Material coefficient

$\sigma_l(\bar{\sigma})$  = Fatigue limit for cycle with mean stress value  $\neq 0$  expressed in terms of maximum stress.

$$\sigma_l(\bar{\sigma}) = \bar{\sigma} + \sigma_{l_0} (1 - b_1 \bar{\sigma}) \quad (5.3)$$

With:

$\sigma_{l_0}$  = Fatigue limit for cycle with mean stress value = 0 expressed in terms of maximum stress.

$b_1, b_2, M$  = Material coefficients

The coefficients of damage laws for Haynes x were determined experimentally and provided by AVIO.

The damage laws were implemented in spread sheets and calculated for various values of loads and temperatures obtaining the Woelher curves:

Figure 5.37- Wohler Curves

FEM simulations of fatigue tests on specimen model were performed: stress-controlled tests at different levels of stress and different temperatures, with stress ratio  $R_\sigma = -1$  and  $R_\sigma = 0$ , both at the frequency 0.5 Hz (LCF) and 50 Hz (HCF). For each test, ten cycles of load were applied until the

material stabilization. The stress analysis results of the last cycle (the stabilized one) were post-processed through Z-Post, applying the Chaboche fatigue model for determining fatigue life of the component, using average and minimum material properties.

Following, the results of the simulation of the HCF test performed at  $R_\sigma = -1$ ,  $T=20^\circ\text{C}$ , frequency 50 Hz and  $\sigma = 460$  MPa. In Figure 5.38, it is shown the stress time history calculated in a node of utilizable length and in Figure 5.39 the stress contour plot in correspondence of the time step of maximum load.

Figure 5.38- Stress [MPa] time [s] history in a node of utilizable length

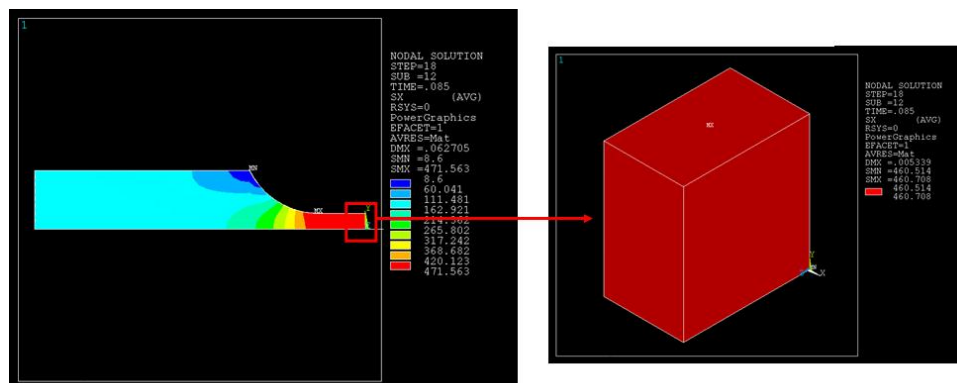

Figure 5.39- Stress contour plot in time step corresponding to the application of maximum tensile load and close up of utilizable length

Following the post-processing of the stress analysis results and fatigue life calculation:

Figure 5.40- Life contour plot in logarithmic scale on the left and on the right, minimum life value (number of cycles to rupture) determined in a node of utilizable length

Where LNF\_S is the number of cycles to failure in logarithmic scale and NF\_S is the number of cycles to failure in linear scale, obtained in a node of utilizable length.

The results obtained by FEM calculations of life have been arranged in Woelher curves.

In Figure 5.41, at different temperatures and in logarithmic scale, it is shown the points in which, the FEM calculated life has been obtained.

Figure 5.41- Comparisons between the life calculated through spread sheets and through FEM

By the comparisons shown in Figure 5.41, life calculated by the damage law implemented in spread sheets and the one obtained through FEM simulations of fatigue tests, it has been possible to validate the procedure of fatigue life calculation.

### 5.3.2 Creep life calculation procedure

In this phase, it has been validated the procedure of creep life calculation.

The model used in this work and implemented in Z-Post is the Rabotnov-Kachanov creep model (Kachanov 1958, Rabotonov 1963, Voza 2002).

The equation that regulated the increment of creep damage is the following:

$$dD = \left( \frac{|\sigma|}{A} \right)^r (1 - D)^{-k} dt \quad (5.4)$$

A, r and k coefficients are typical for each material and are determined through a serie of uniaxial creep experimental tests, at constant level of  $\sigma$  and constant temperature. For each test condition, it is calculated the creep time to rupture  $t_R$ .

Extracting  $dt$  from the previous formula and integrating with fitted boundary conditions, it gets:

$$t_R = \frac{1}{k+1} \left( \frac{|\sigma|}{A} \right)^{-r} \quad (5.5)$$

Once known the cycle duration, it is possible to determine the time number of cycles to creep rupture.

The coefficients of the damage laws were determined experimentally and provided by AVIO.

The damage law was implemented in spread sheets and calculated for various values of loads and temperatures obtaining the creep curves:

Figure 5.42- Creep curves

FEM simulations of creep tests on specimen model were performed: stress-controlled tests at different levels of stress and different temperatures, with stress ratio  $R_\sigma = 0$ .

The applied load cycle is the following:

Figure 5.43- Creep test load cycle

In which: load time  $\Delta t_1 = 10\text{s}$ , unload time  $\Delta t_3 = 10\text{s}$ , hold time  $\Delta t_2 = 3600\text{s}$

The stress analysis results were post-processed through Z-Post, applying the Rabotonov-Kachanov creep model for determining creep life of the component, using average and minimum material properties.

Following, the results of the simulation of the creep test performed at  $R_\sigma = 0$ ,  $T=600^\circ\text{C}$  and  $\sigma = 450$  MPa. In Figure 5.44, the stress contour plot in correspondence of the time step  $t = 10\text{s}$  at the end of loading phase and corresponding to the application of maximum tensile load. In the same figure, on the right, the close up of utilizable length.

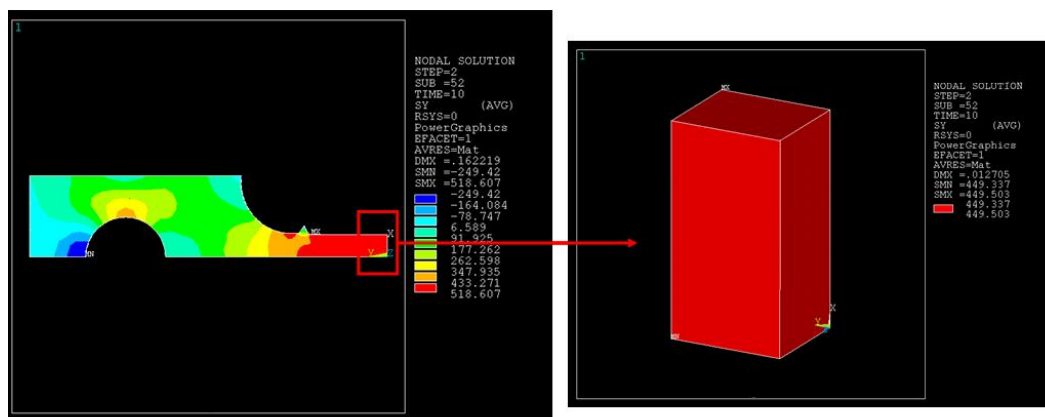

Figure 5.44- Stress contour plot in time step  $t=10s$  and close up of utilizable lenght

Following the post-processing of the stress analysis results and creep life calculation:

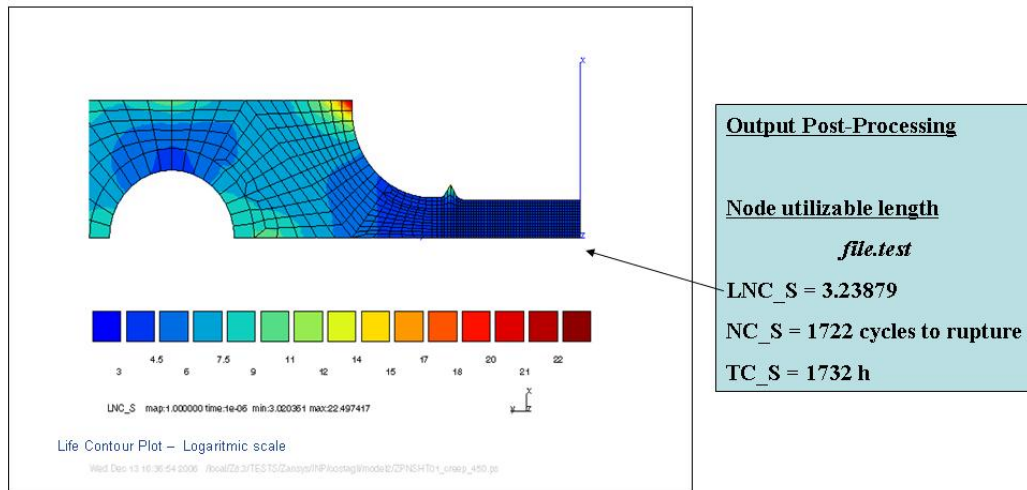

Figure 5.45- Life contour plot in logarithmic scale on the left and on the right, minimum life value (number of cycles to rupture and time to rupture) determined in a node of utilizable length

Where LNC\_S is the number of cycles to failure in logarithmic scale, NC\_S is the number of cycles to failure in linear scale, and TC\_S is time to creep rupture, obtained in a node of utilizable length.

The results obtained by FEM calculations of life have been arranged in the graph of creep curves.

In Figure 5.46, at different temperatures and in logarithmic scale, it is shown the points in which, the FEM calculated life has been obtained

Figure 5.46- Comparisons between the life calculated through spread sheets and through FEM

By the comparisons in Figure 5.46, that show life calculated by the damage law implemented in spread sheets and the one obtained through FEM simulations of creep tests, it has been possible to validate the procedure of creep life calculation.

### 5.3.3 Creep-fatigue life calculation procedure

In this phase, it has been validated the procedure of life calculation of a component considering the non-linear interaction between fatigue and creep.

Damage non-linear accumulation theory is here utilized to apply a damage accumulation model able to predict life of a structural component, considering a non-linear interaction mechanism between creep and fatigue (Lemaitre and Chaboche, 2000). This model is implemented in Z-Post.

The number of cycles to rupture  $N_F$ , obtained considering only fatigue contribution, has been calculated using the Chaboche model introduced at paragraph 5.3.1. The time to rupture and  $N_C$  number of cycles to rupture, obtained considering only creep contribution, have been calculated through the Rabotnov-Kachanov creep model introduced at paragraph 5.3.2.

It is possible to calculate damage evolution (from  $D_i$  to  $D_f$ ), inside each cycle, according to the following formulas:

$$\frac{1}{N_C} = (1 - D_i)^{k+1} - (1 - D)^{k+1} \quad (5.6)$$

And

$$\frac{1}{N_F} = \left[ 1 - (1 - D_f)^{\beta+1} \right]^{1-\alpha} - \left[ 1 - (1 - D)^{\beta+1} \right]^{1-\alpha} \quad (5.7)$$

Where:

$$\alpha = 1 - a \cdot \left( \frac{\sigma_{Max} - \sigma_l}{\sigma_u - \sigma_{Max}} \right) \quad (5.8)$$

Numerical simulations of creep-fatigue tests were performed: stress-controlled tests, at  $R\sigma = 0$ , different levels of load and different temperatures, with time of load application and hold time varying according to the following table:

Test case	Time of load application [s]	Hold time [s]
1	10	0
2	10	10
3	10	90
4	10	3600
5	1	0
6	1	10
7	1	90
8	1	3600
9	0.01	0
10	0.01	10
11	0.01	90
12	0.01	3600

Table 5.4 – Conditions for performing simulations of creep-fatigue tests

To validate the life calculation procedure, the damage evolution laws have been implemented in a FORTRAN algorithm, and the results have been compared with the ones obtained by FEM simulations of creep-fatigue tests (the results were post-processed through Z-Post).

By the correspondence between the values of life evaluated by FEM calculations and by the damage laws implemented in a FORTRAN algorithm, it has been possible to validate the procedure of life calculation considering the non-linear interaction between the two damage mechanisms.

The results of creep and fatigue models implementation, are that considering non-linear damage accumulation, the evolution of creep-fatigue life calculation is significantly different.

Figure 5.47- Damage cumulation – Linear vs non-linear cumulation

In this way, it is clear that life calculation of a component can give significantly different results if compared to linear superimposing of effects principle.

#### 5.4 Elasto-visco-plastic analysis on combustion chamber of aeronautical engine SaM146

At the paragraph 5.2 it has been described the methodology developed to perform elasto-visco-plastic analysis on structural components. Moreover, it has been shown the effectiveness of the EVP material model.

In this section, it will be presented the results obtained by performing elasto-visco-plastic analysis on the combustion chamber of an aeronautical engine. The objective of the analysis is to determine the stress state in the structure under a simplified typical mission, taking into account fatigue and creep interaction. Besides, structure life has been determined considering the interaction between the two damage mechanisms since for components that work at high temperature, the critical zone and number of cycles to failure are not correctly predicted by linear-elastic analysis. The number of cycles to failure in pure fatigue and in pure creep have been computed too. Moreover, the computing time has been evaluated, since stress analysis of a combustor subjected to a complex mission is highly time-consuming, for both the FEM model size and the complexity of the mission.

The life assessment procedure has been made available.

The FEM model of the combustion chamber has been realized with brick elements (Figure 5.48). The model represents a sector of 20° cyclically symmetrical, that includes 3D features. Impingement and effusion cooling holes are not modeled.

The following components are been modeled:

- Bolted cowl
- Dome
- Splash plate
- Outer flange/liner
- Inner flange/liner

Figure 5.48- Combustion chamber – FEM model

The main FEM model features are:

Nodes	29491
Elements	18172
Element Type	3D Solid (nodes:8)

Table 5.5 – FEM model features

In order to take into account of the effect of temperature and loading waveform on the materials behaviour in EVP regime, a simplified start-stop load cycle has been chosen. The baseline start-stop

load cycle represents a simple model, based on a 500 s ramp up until master design point (MDP) condition is reached, 4500 s hold-time and 500 s ramp down until no-load condition. (Figure 5.49)

Figure 5.49 - Thermal loads – Time history

This simplified load cycle refers to a typical mission (full deteriorated, Figure 5.50). The intent is:

- To represent realistic working conditions, taking into account the ramp up/down times and hold time as well;
- To reach a stabilized response (stress, LCF, creep) save computing time and evaluate the time requirements to run a full mission.

With the aim to give an immediate comparison, the simplified start-stop baseline load cycle has been overlapped to full deteriorated mission as shown in Figure 5.50. The temperature map, at the end of the ramp up load, is shown in Figure 5.51.

Figure 5.50 - Thermal loads – Typical mission full deteriorated

Figure 5.51 - Thermal loads – Maximum values [°C]

Following, it is shown the FEM model boundary conditions.

Cyclic symmetry constraints have been applied on the cut sections of the symmetric base sector (Figure 5.52).

Figure 5.52 – FEM model boundary condition - Cyclic symmetry constraints

On the bolted head flanges area, the average displacements in the tangential direction have been imposed equal to zero. On the flanges outer edges, axial constraints have been imposed (Figure 5.53).

Figure 5.53 – FEM model boundary condition - Flanges

In order to simulate combustor components assembly, linear relationships (constraint equations, also indicated as CE) between degrees of freedom have been used. In the head bolted areas, radial, tangential and axial CE have been imposed. In the flanges area only radial CE have been imposed (Figure 5.54).

Figure 5.54 – FEM model boundary condition – Constraint equations

The elasto-visco-plastic model of Haynes x has been implemented.

In order to achieve stress and life stabilization, thirteen start-stop cycles were run (Figure 5.49).

Following, the stress contour plots of the first and thirteenth cycles are presented. Particularly, the results are shown in the most critical time points, corresponding to maximum load (time points A and B) and minimum load (time point C), see Figure 5.55.

Figure 5.55 – Critical time points

The Figure 5.57 shows Von Mises stress calculated in time point A of the first load cycle (Figure 5.56). Moreover, in the same figure, the node 20107 is the node characterized by the minimum life, as it will be shown later.

Figure 5.56 – Critical time point A – Cycle 1

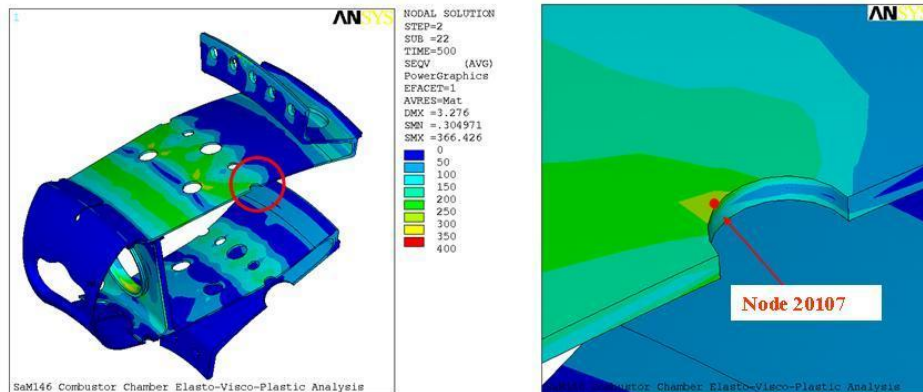

Figure 5.57 – Von Mises stress contour plot in time point A of the first cycle

In Figure 5.58, it is shown Von Mises stress calculated in point B of the first cycle, and it is possible to observe the stress relaxation in comparison with the Von Mises stress calculated in point A.

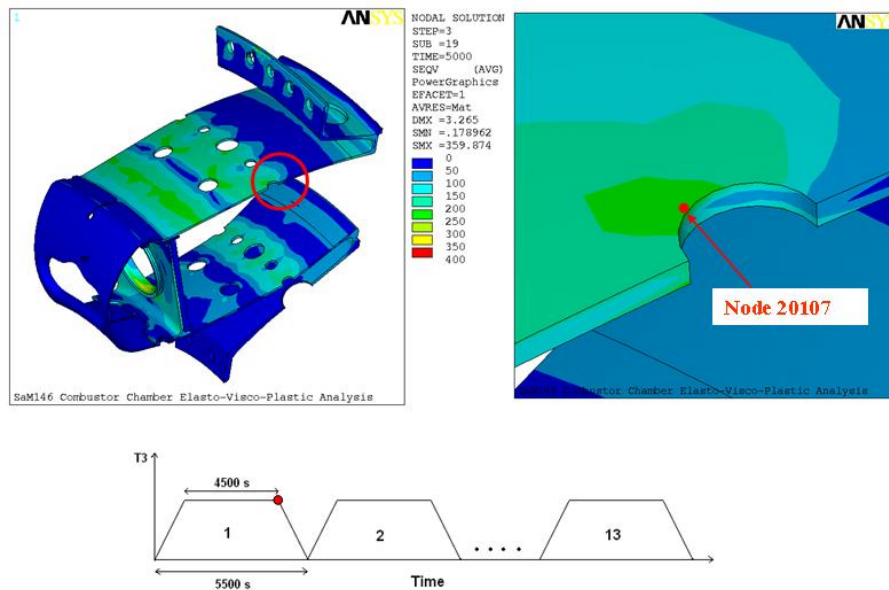

Figure 5.58 – Von Mises contour plot in time point B of the first cycle

In Figure 5.59 it is shown the results obtained in the last critical time point, C, of the first cycle.

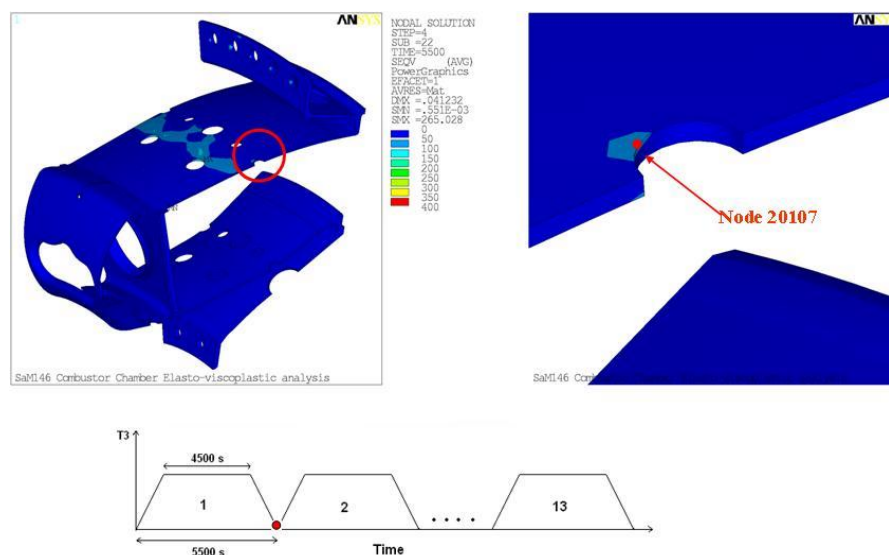

Figure 5.59 – Von Mises contour plot in time point C of the first cycle

Following, from the Figure 5.60 to Figure 5.62, the Von Mises stress calculated in the same critical time points (A,B,C) but in the last load cycle, are now presented.

Figure 5.60 – Von Mises contour plot in time point A of the thirteen cycle

Figure 5.61 – Von Mises contour plot in time point B of the thirteen cycle

Figure 5.62 – Von Mises contour plot in time point C of the thirteen cycle

Following, the most significant analysis results.

In Figure 5.63, it is shown the stress time history of the first cycle calculated in the critical node 20107 (minimum life), in which it is possible to observe the material stress relaxation from time point A to time point B in correspondence of the same maximum load.

Figure 5.63 – Von Mises stress time history of node 20107 – cycle 1

In Figure 5.64 it is shown the stress time history of the thirteen cycle calculated in the same node. By observing the stress values between the time points A and B, it is possible to consider the behaviour material stabilized.

The cyclic stress stabilization is more evident in Figure 5.65, where the stress time history of all cycles, calculated in node 20107, are shown and it is possible to observe also the envelopes of maximum and minimum stress.

Figure 5.64 – Von Mises stress time history in node 20107 – cycle 13

Figure 5.65 – Von Mises stress time history in node 20107 – all cycles

In order to verify the material stabilization, the envelopes of maximum and minimum stress are also presented in the Table 5.6 and Table 5.7. By the values reported in the tables, it is possible to observe that the stress variation between the two final instants is less than 1.5%. This lets us to consider the material behaviour stabilized.

Time [s]	$\sigma$ [Mpa]	$\Delta$ [Mpa]	$\Delta$ %
500	274.93		
6000	238.08	36.9	13.4
11500	226.38	11.7	4.9

66500	-150.96	2.1	1.4
72000	-152.88	1.9	1.3

Table 5.7 Minimum stress envelope

It is possible to conclude that the results obtained by elasto-visco-plastic analysis on a real component are in agreement with expected results, in fact the implementation in FEM codes of complex material models, allows to simulate the real material behaviour and to take into account the non-linear interaction between creep and fatigue for structural analysis.

Moreover, one of the objectives of the analysis has been also to evaluate the computing CPU time, in order to evaluate the time requirements to run a full mission, in a next phase of the activity. In particular, the total CPU time at the end of the first start-stop load cycle has been 35078 seconds (9.74 hours).

## 5.5 Evaluation of creep and fatigue life

The methodology of life calculation, previously applied and validated on specimens used for fatigue-creep tests, has been here applied to a real component.

In fact, a further objective of the analysis performed on the combustion chamber was to make available the life evaluation procedure, by starting from the implementation of an elasto-visco-plastic material model able to take into account the nonlinear interaction between creep and fatigue.

The life of the structure has been calculated through the module Z-Post of Z-Mat, which allows to post-processing the results obtained by the elasto-visco-plastic analysis. In particular, the local post-processing allows studying the variables evolution in the time, once fixed a part of the structure. The calculation is made in nodes, starting from the data saved in a file given in input to Z-Post, together with the stress analysis results file and the Z-Mat file containing the values of coefficients material model. Z-Post module implements various damage models and allows calculating component life under complex cyclic loads.

The damage non-linear accumulation theory has been utilized to apply a damage accumulation model able to predict life of the structural component considering a non-linear interaction mechanism between creep and fatigue. The number of cycle to failure,  $N_F$ , obtained by considering pure fatigue and the number of cycle to failure,  $N_C$ , obtained by pure creep, have been calculated respectively by Chaboche and Rabotnov-Kachanov theories introduced at paragraphs 5.3.1 and 5.3.2.

In according with these laws, the evolution of the damage (from  $D_i$  to  $D_f$ ) inside each cycle has been calculated by the equations introduced at paragraph 5.3.3.

Following, the life calculation results are presented. In particular, it is shown the hysteresis cycles obtained by stress analysis and calculated in the critical nodes and and the life versus cycles plots calculated in the same nodes:

- In node 20107 (located in outer liner) minimum creep life has been verified.
- In node 20194 (located in outer liner) minimum fatigue life has been verified.

The Figure 5.66 shows the hysteresis cycles calculated in node 20107 and the Figure 5.67 shows the values of creep life versus cycles.

Figure 5.66 – Hysteresis cycle in node 20107

Figure 5.67 – Creep life in node 20107

In Figure 5.68 it is shown the creep life contour plot in logarithmic scale on the structure. It is highlighted the critical area, where it is located the node in which minimum creep life has been determined.

Figure 5.68 – Creep life contour plot

In Figure 5.69, it is shown the position of the node 20194 in FEM model. This is the node where minimum fatigue life has been verified.

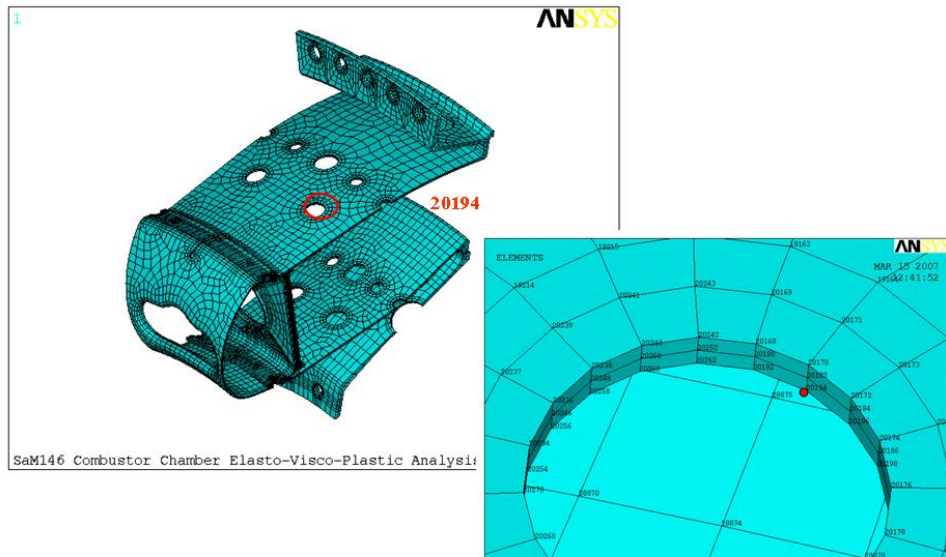

Figure 5.69 – Position of node 20194 in FEM model

In Figure 5.70 and Figure 5.71 Von Mises stress time history and hysteresis cycles calculated in node 20194 and obtained by elasto-visco-plastic analysis, are shown.

In Figure 5.72, it is shown the fatigue life versus cycles calculated in the same node.

Figure 5.70 – Von Mises stress time history in node 20194

Figure 5.71 – Hysteresis cycles in node 20194

Figure 5.72 – Fatigue life vesus cycles in node 20194

Following, in Figure 5.73, the fatigue life contour plot in logarithmic scale on the structure. In figure, it is possible to observe the critical area in which minimum fatigue life has been determined.

Figure 5.73 – Fatigue life contour plot

Finally, in the Figure 5.74, it is shown, on the full FEM model, the contour plot of the number of cycles to failure calculated by taking into account the non-linear interaction between creep and fatigue, obtained applying the Chaboche theory of nonlinear accumulation of damage. The contour plot is presented in logarithmic scale.

Figure 5.74 – Life contour plot

In the table, it is presented a summary of the results obtained:

Node	Zone	$T_{max}[^{\circ}C]$	Cycle N°13 Stress [MPa]				Cycle N°13 Minimum life		
			$\sigma_{min}$	$\sigma_{max}$	$\sigma_m$	$\sigma_a$	NR	NC	NF
20107	Outer Liner	702	-153	192	20	173	1362	1365	$> 10^7$
20194	Outer Liner	731	-217	326	54	272	12460	14139	6543818

Table 5.8 – A summary of results

In particular in the Table 5.8, it is shown the maximum and minimum stress calculated in the two critical nodes, in the thirteen cycle, and the values of medium and alternate stress. Moreover, it is possible to observe the values of minimum number of cycle to failure (NR), and the number of cycle to failure calculated in pure fatigue (NF) and pure creep (NC). The results show that the critical area is located at node 20107.

In this way, a new procedure of life calculation has been developed and made available in order to take into account the interaction between the two damage mechanisms for evaluating in a more careful way the operative life of structures.

The developed procedure for implementing in FEM codes complex material models, able to simulate the real behaviour of materials and to take into account the non-linear interaction between creep and fatigue for structural analysis and life prediction, allows improving significantly the designing of structural components. In fact, the capability of reproducing the real material behaviour and predicting the component life in a more dependable way, allow reducing the traditional factors of safety that are overly conservative and preventing from achieving the optimal efficiency in structural designing process.

## 5.6 Elasto-visco-plastic analysis on a portion of a turbine blade

In this section, it has been developed a procedure for implementing complex material models in FEM codes and performing elasto-visco-plastic analysis on structural components.

It has been shown the results obtained by the implementation of an elasto-visco-plastic model already characterized for performing stress analysis on the combustion chamber of aeronautical engine and calculating structure life.

It will be now presented the results obtained by performing a preliminary structural analysis on a portion of turbine blade, implementing the elasto-visco-plastic model of Renè 80 characterized at the previous chapter. As seen, because of the insufficient experimental data base, the developed material model may not have a general character and not describe correctly material behaviour, above all in terms of stress relaxation and viscosity at high temperature.

The FEM model of the portion of turbine blade has been realized (Figure 5.75).

Figure 5.75 – FEM model

The main FEM model features are:

Nodes	156582
Elements	42503
Element Type	3D Solid (nodes:20)

Table 5.9 - FEM model features

Following, the FEM model boundary conditions:

- radial constraints on the lower surface of the blade
- $u_x$  and  $u_y = 0$  in the nodes of trailing edge (axial and tangential constraints)
- equal radial displacement in the nodes of upper surface (CP constraints)

Figure 5.76 – FEM model constraints

Figure 5.77 – FEM model – CP constraints

The blade is lapped on the airfoil by hot gas in expansion ( $T > 800^{\circ}\text{C}$  in base-load) and on the internal channels by the air spilled by compressor ( $T > 300^{\circ}\text{C}$  in base-load). By convection, hot gases give up heat to the blade through airfoil surface; while the air that laps the surface of internal channels takes away heat (see Figure 5.78).

Figure 5.78 – Conditions of thermal exchange

The typical thermomechanical cycle applied to the turbine blade is the following:

Figure 5.79 – Thermomechanical loads

Where HTC are convection coefficients and T\_Bulk are bulk temperatures of gas.

For reserve of industrial data, it is not possible to show the values of the mission.

In this phase a simplified mission (T\_Bulk versus time) has been applied (Figure 5.80). Twenty cycles have been repeated in order to achieve material stabilization:

Figure 5.80 – Simplified load cycle

The time points A and B indicated in Figure 5.80 correspond respectively at the beginning and the end of base load (maximum load).

The elasto-visco-plastic material model characterized at the section 4.4 was implemented.

Following the stress analysis results, in particular it is shown the Von Mises stress time history calculated in one of the critical nodes (where maximum stress has been determined). It is possible to observe material stabilization after twenty cycles (Figure 5.81).

Figure 5.81 – Von Mises stress time history calculated in a critical node – all cycles

Following, the Von Mises stress contour plot calculated in the first cycle at the beginning of the base-load (maximum load): time point  $t = 1600s$  (Figure 5.82).

Figure 5.82 – Von Mises stress contour plot calculated in the first cycle at  $t = 1600s$

Following, the Von Mises stress contour plot calculated in the first cycle at the end of the base-load (maximum load): time point  $t = 8200s$  (Figure 5.83).

Figure 5.83 – Von Mises stress contour plot calculated in the first cycle at  $t = 8200s$

Following, the Von Mises stress contour plot calculated in the last cycle at the beginning of the base-load (maximum load): time point  $t = 221600s$  (Figure 5.84).

Figure 5.84 – Von Mises stress contour plot calculated in the last cycle at  $t = 221600s$

Following, the Von Mises stress contour plot calculated in the last cycle at the end of the base-load (maximum load): time point  $t = 228200s$  (Figure 5.85).

Figure 5.85 – Von Mises stress contour plot calculated in the last cycle at  $t = 228200s$

From the Figure 5.82 and Figure 5.83 it is possible to observe the time-dependent material model behaviour: the results show, in fact, the stress relaxation that the component has during its steady state condition.

The two stress contour plots show the same structure, in the same cycle at the end of the start up sequence and before the shut down procedure. In this specific case 6600s have been considered.

From the Figure 5.84 and Figure 5.85 it is possible to observe the stabilization of material: in the last cycle, in fact, the stress remain constant from the time point A to B (from the beginning to the end of base load).

It is necessary to point out that the highlighted stress relaxation (Figure 5.82 and Figure 5.83) is low, since the material model is not still optimized.

As seen, during the process of material characterization it was not possible to optimize the viscous parameters of the model because of dependable experimental data (tensile tests at different strain rate, relaxation tests) were lacking. For this reason, as expected, the stress analysis results have shown a predictive capability of the model not still sufficient. However, the presently obtained numerical results may be considered to be reasonable, if the scarcity of available experimental data is kept in mind.

Better results may be obtained integrating the experimental data base with new tests opportunely designed for the characterization process and determining the optimized set of model coefficients.

## 6 Concluding Remarks

To introduce innovation in high temperature components design, it is essential to accurately assess structural integrity of the components for long-term elevated temperature service and thereby to reduce the unduly overconservatism in the design. In order to evaluate creep-fatigue damage and cumulative inelastic strains, it is required to perform detailed inelastic analysis for predicting accurately the stress/strain history taking into account both time independent and time dependent material deformation behaviour. Since the stress/strain response of the components is closely related to life prediction, the reliability of life prediction depends strongly on the adequacy of the constitutive models employed in the analysis.

Among various viscoplastic models available in literature, the Chaboche viscoplastic model is found to be superior for high temperature components applications (as gas turbine blades and combustion chamber of jet engines) because of its ability to simulate, with reasonable accuracy, all the essential mechanical behaviour of Ni-base superalloys in the temperature range of 400-1000°C under monotonic and cyclic loading conditions.

The strength of this model is in the possibility to use multi-potential mechanisms for cases of time independent plasticity in combination with viscoplastic deformation. Potentials represent inelastic dissipations which describe the evolution of independent inelastic deformation mechanisms. In this way, total strain may be partitioned into the reversible or elastic strain and the irreversible or inelastic strain. The latter can be further separated into plastic and viscoplastic strain. The result is refined modelling of a wide range of strain rates associated with different deformation mechanisms, in this way each potential can have its own flow law and hardening mechanism independently from the other ones. Besides, Chaboche model allows the superimposition of isotropic hardening on nonlinear kinematic hardening resulting in a modification of the elastic domain by translation and uniform expansion. This allows describing the progression of hardening for materials subjected to cyclic loads. Besides, differently from others kinematic hardening models analysed in literature (for example Prager model), the evolution of the kinematic variable in the time is defined in way to take into account the effects due to the deformation history. This model allows considering a hardening which changes with continuity, with the advantage to describe the nonlinearity of cyclic plastic deformation process.

However, it has been shown that one major limitation of Chaboche model is in its high number of parameters and accordingly in a lot of material data required to identify them.

The developed work has allowed a detailed analysis of material characterization process and has led to the application of the Chaboche elasto-visco-plastic model to a Nickel base superalloy used in high temperature components of gas turbines and jet engines. The constitutive equations were defined in way to be able to predict material behaviour under repeated cyclic loads and high temperatures. In particular, two dissipation potentials have been utilized to accurately capture the material loading-rate sensitivity, since each of them describe the evolution mechanisms of inelastic deformations associated respectively to slow and high strain rates. Moreover, it has been shown how the superposition of two kinematic hardening models provide a significantly better response in representing the real material behaviour over the entire strain range, compared to a single kinematic hardening model. This choice allowed smoothing out the transition from linear to nonlinear behaviour and modelling short and long-range hardening mechanisms.

The developed elasto-visco-plastic model with isotropic and kinematic hardening combines plasticity and creep and allow taking into account of material behaviour rate dependence.

Material characterization process has been developed through the following phases:

- Choice of the characteristic tests and interpretation of the mechanical quantities  $\sigma(t)$ ;  $\varepsilon_p(t)$ .  
This choice depends on the envisaged field of application:
  - initial loading
  - stabilized cycle
  - transient cyclic effects.
- Identification of model coefficients: this has been the most difficult step (high number of involved parameters).

Identification can be defined as the work consisting in specifying the functions which appear in the model and in finding the numerical values of the coefficients which define the functions for each material. It has been shown how this represents a very difficult task since it does not follow any rigorous rule and in which experience and “art of building a model” play a major role in steering between theory and experiment. This involves a procedure of parameters identification that is still too artful and far to be standardized.

The initial parameters, given by tentative, have been fitted to the real curves through an iterative process of optimization based on mean square values technique. It has been necessary to turn out to a step-by-step procedure of characterization, adding tests and the corresponding sensitive parameters progressively into the optimization loop. In a such procedure, the previously calibrated coefficients provide good starting points for the next step, thus allowing the algorithm to escape from local minima. At the end, all tests have to be added and all coefficients identified at the same time, for obtaining a good set of coefficients.

However, in spite of a step by step procedure was applied, many problems of convergence of the optimization tool were verified. In fact, many coefficients are strongly depending one each other; further in absence of a good experimental data base, a non correct identification of one of these parameters, implies the not convergence of the solution during the optimization process.

As it was introduced at the beginning of the work and subsequently examined, the most important and often times most difficult, aspect of modeling material behaviour at elevated temperature is obtaining the required material functions for viscoplasticity and associated material parameters. The difficulty associated with this process stems from not only the variety in mathematical forms for the material functions, but also the fact that given the material functions there is no unique set of material parameters for any given load path. Therefore, numerous iterations and difficult compromises are required before a final set of material parameters (for the assumed material functions) can be obtained. The developed work has highlighted how these aspects are particularly true when dealing with models that possess a very large number of material constants that:

- are often lacking in their direct physical interpretation
- may have vastly different magnitudes
- are highly interactive one each other.

On the other hand, the number of coefficients represents the price to pay for obtaining a model which has the ambition of becoming a law. In fact, the result of material characterization process has to be a model with a general character, so that while identified only by a restricted number of experiments, it is representative of other types of experiments with a predictive capability. The totality of the situations verified by a model is its field of validity. This characterizes the goodness of the model and

is expressed qualitatively by the set of all possible variation histories of the variables and quantitatively by the range of the variations within which the model agrees with the physics.

In Chapter 4, it has been widely shown that a model cannot be identified correctly unless a sufficient number of test results are available, which embrace a significant range of variation of each parameter. Otherwise, we run the risk of not determining one or more coefficients well enough. Moreover, it has been verified how quality of performed experiments has affected the characterization process leading to a significant reduction of utilizable experimental tests because of too scattered data and numerous uncertainties, losing in material model generality.

As shown and already dealt with detail at the section on the design of experiments, some guidelines have been provided in order to perform a complete process of material characterization and to determine a set of optimized parameters for Chaboche elasto-visco-plastic model. First of all, two different groups of tests have to be designed: for characterization and validation processes respectively. In particular, tests within the reversible domain (i.e., creep with recovery upon complete unloading, and relaxation) and experiments conducted within the irreversible domain (i.e., relaxation, conventional creep, multi-step creep, tensile curves at different total strain rates) have to be used for characterization; while multiple-step relaxation, cyclic and plasticity/creep interaction tests have to be reserved for validating the predictive behaviour of the model.

It was then shown the necessity to separate the characterization process in more stages in order to reduce the convergence problems of solution:

1. Determining viscous flow and initial yield stress using tensile curves at different total strain rates. This kind of tests allows calibrating the viscous effects and the dependence of material behaviour by loading-rate.
2. Determining hardening parameters by LCF tests and LCF-step tests, in particular by cyclic curve and stabilized loops.
3. Determining thermal recovery parameters by providing relaxation, conventional creep and multi-step creep tests while keeping the flow and hardening parameters estimates from step 1 and 2 fixed. These kinds of tests allow describing the time-dependent (short-term and long-term) material behaviour.
4. Fit all tests at one time to obtain final parameter estimates, this is accomplished by allowing all visco-plastic parameters to be active (using the material parameters found in steps 1, 2 and 3 as initial starting values) but with tight upper and lower bounds around each parameter.

In the designing of experimental tests, it is important to consider that if one went to focus on only one type of loading condition, superior correlations could of course be achieved for that class of loading. However, predictions of other classes of loading may severely suffer. For example, during a separate characterization process involving only tensile tests, excellent correlation was obtained, but at the expense of poor creep and relaxation behaviour for a given set of material parameters. Conversely, when the model was calibrated for creep responses, poorer tensile and relaxation behaviours were similarly predicted. Thus when judging the “goodness” of a given model, it must keep in mind the appropriate required “data content” for accurately capturing the full range of material behaviour of interest. For an identical material and model, it may be necessary to define several sets of coefficients, each better suited to a domain of variation or to a load type, for example, rapid transient loads, short-term loads, long-term loads and stationary loads.

The careful analysis of material characterization process has allowed developing a procedure for implementing in FEM codes complex material models, able to simulate the real material behaviour and to take into account the non-linear interaction between creep and fatigue for structural analysis and life prediction. A procedure of structural analysis has been developed through the comparison with procedures of tested validity, in way to allow a correct and safe implementation of elasto-visco-plastic material models. In particular, starting from an elasto-visco-plastic material model, already characterized and validated, it has been possible to test its effectiveness by performing comparison analysis with known models in linear-elastic and elasto-plastic fields.

As discussed in Chapter 5, the procedure has been developed and validated on a test case and then applied to a combustion chamber of aeronautical engine. The obtained results are in agreement with the expected ones: the implementation of an elasto-visco-plastic model in FEM code has allowed simulating the physical phenomena, stress relaxation and cycle stabilization, which may be appreciated only through an analysis performed with a *rate dependent* material model.

As a matter of fact, the elasto-visco-plastic model doesn't consider the *time* variable as a simple counter, that scans the succession of load configurations, but associates to it the real physical meaning. In this way both the loads application and material behaviour become *rate dependent*.

For this reason, the material model is able to simulate at once, fatigue and creep under thermomechanical loads for long time and the effect of "diffusion" that creep causes.

Besides, structure life has been determined considering the nonlinear interaction between the two damage mechanisms since for components that work at high temperatures, critical zone and number of cycles to failure are not correctly predicted by linear elastic analysis and the simple superimposing of creep and fatigue damage is too conservative for actual industrial needs.

The important contribute that the present work will provide to industrial applications is in the development of a procedure that improves significantly the design of structural components through the implementation of elasto-visco-plastic material models. In fact, the capability of simulating the real material behaviour and predicting the component life in a more dependable way by taking into account the nonlinear interaction between fatigue and creep, allow reducing the traditional factors of safety that are overly conservative and preventing from achieving the optimal efficiency in structural designing procedure.

It has been shown also the response obtained by implementing the material model not completely characterized in Chapter 4 because of the available experimental data base was not sufficient. The results of an elasto-visco-plastic analysis performed on a portion of turbine blade have shown that the developed model is able to capture the *rate dependent* material behaviour but, as expected, its predictive capability is not still sufficient.

As widely shown and examined until now, it is important to highlight that material characterization process and implementation of complex user-defined material models in FEM software are then the results of procedures still far off to be standardized and above all are affected by the choice which the analyst do on the base of his experience. Besides, it is a slow and expensive process and doesn't assure the result.

However, the required steps have been highlighted in order to get a correct and complete characterization process.

## Appendix A Definitions and base assumptions

One of the most challenging engineering research fields, is to be able to simulate the material behaviour not only in ordinary conditions, but especially when it is subjected to large deformations. To reach this goal is of primary importance to exactly define its elastic field in order to build the most solid bases to schematize its plastic behaviour.

### A.1 Elasticity

A material is said to be elastic if it deforms under stress (e.g., external forces), but then returns to its original shape when the stress is removed. The amount of deformation is the strain. The elastic regime is characterized by a linear relationship between stress and strain, denoted linear elasticity. This idea was first stated by Robert Hooke in 1675 as a Latin anagram whose solution he published in 1678 as "*Ut tension, sic vis*".

This linear relationship is called Hooke's law that states that the amount by which a material body is deformed (the strain) is linearly related to the force causing the deformation (the stress). Materials for which Hooke's law is a useful approximation are known as linear-elastic or "*Hookean*" materials. The classic model of linear elasticity is the perfect spring.

Its extension, strain, is linearly proportional to its tensile stress,  $\sigma$  by a constant factor, the inverse of its modulus of elasticity,  $E$

$$\sigma = E\varepsilon \quad (1)$$

Steel exhibits linear-elastic behaviour in most engineering applications. Hooke's law is valid for it throughout its elastic range (i.e., for stresses below the yield strength). For some other materials, such as aluminium, Hooke's law is only valid for a portion of the elastic range. For these materials a proportional limit stress is defined, below which the errors associated with the linear approximation are negligible.

### A.2 Tensor Expression of Hooke's Law

When working with a three-dimensional stress state, a 4<sup>th</sup> order tensor ( $c_{ijkl}$ ) must be defined. Containing 81 elastic coefficients to link the stress tensor ( $\sigma_{ij}$ ) and the strain tensor (or Green tensor) ( $\varepsilon_{kl}$ ).

$$\sigma_{ij} = \sum_{kl} c_{ijkl} \cdot \varepsilon_{kl} \quad (2)$$

Due to the symmetry of the stress tensor, strain tensor, and stiffness tensor, only 21 elastic coefficients are independent. As stress is measured in units of pressure and strain is dimensionless, the entries of  $c_{ijkl}$  are also in units of pressure.

### A.3 Linear Elasticity

Linear elasticity is the mathematical study of how solid objects deform and become internally stressed due to prescribed loading conditions. Linear elasticity relies upon the continuum hypothesis and is applicable at macroscopic (and sometimes microscopic) length scales. Linear elasticity is a simplification of the more general nonlinear theory of elasticity and is a branch of continuum mechanics.

The fundamental "*linearizing*" assumptions of linear elasticity are: "small" deformations (or strains) and linear relationships between the components of stress and strain. In addition linear elasticity is only valid for stress states that do not produce yielding. These assumptions are reasonable for many engineering materials and engineering design scenarios. Linear elasticity is therefore used extensively in structural analysis and engineering design, often through the aid of finite element analysis.

### A.4 Isotropic Material

Isotropic materials are characterized by properties which are independent of direction in space. Physical equations involving isotropic materials must therefore be independent of the coordinate system chosen to represent them. The strain tensor is a symmetric tensor. Since the trace of any tensor is independent of coordinate system, the most complete coordinate-free decomposition of a symmetric tensor is to represent it as the sum of a constant tensor and a traceless symmetric tensor. Thus:

$$\varepsilon_{ij} = \left( \frac{1}{3} \varepsilon_{kk} \delta_{ij} \right) + \left( \varepsilon_{ij} - \frac{1}{3} \varepsilon_{kk} \delta_{ij} \right) \quad (3)$$

Where  $\delta_{ij}$  is the Kronecker delta. The first term on the right is the constant tensor, also known as the pressure, and the second term is the traceless symmetric tensor, also known as the shear tensor.

The most general form of Hooke's law for isotropic materials may now be written as a linear combination of these two tensors:

$$\sigma_{ij} = 3K \left( \frac{1}{3} \varepsilon_{kk} \delta_{ij} \right) + 2G \left( \varepsilon_{ij} - \frac{1}{3} \varepsilon_{kk} \delta_{ij} \right) \quad (4)$$

Where K is the bulk modulus and G is the shear modulus.

Using the relationships between the elastic moduli, these equations may also be expressed in various other ways. For example, the strain may be expressed in terms of the stress tensor.

In isotropic media, the elasticity tensor gives the relationship between the stresses (resulting internal stresses) and the strains (resulting deformations). For an isotropic medium, the elasticity tensor has no preferred direction: an applied force will give the same displacements (relative to the direction of the force) no matter the direction in which the force is applied. In the isotropic case, the elasticity tensor may be written:

$$C_{ijkl} = K\delta_{ij}\delta_{kl} + \mu\left(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk} - \frac{2}{3}\delta_{ij}\delta_{kl}\right) \quad (5)$$

Where  $K$  is the bulk modulus (or incompressibility), and  $\mu$  is the shear modulus (or rigidity), two elastic moduli. If the medium is homogeneous as well, then the elastic moduli will not be a function of position in the medium. The constitutive equation may now be written as:

$$\sigma_{ij} = K\delta_{ij}\epsilon_{kk} + 2\mu\left(\epsilon_{ij} - \frac{1}{3}\delta_{ij}\epsilon_{kk}\right) \quad (6)$$

This expression separates the stress into a scalar part on the left which may be associated with a scalar pressure, and a traceless part on the right which may be associated with shear forces. A simpler expression is:

$$\sigma_{ij} = \lambda\delta_{ij}\epsilon_{kk} + 2\mu\epsilon_{ij} \quad (7)$$

Where  $\lambda$  is Lamé's first parameter.

## A.5 Yield

The yield strength or yield point of a material is defined in engineering and materials science as the stress at which a material begins to deform plastically. Prior to the yield point the material will deform elastically and will return to its original shape when the applied stress is removed. Once the yield point is passed some fraction of the deformation will be permanent and non-reversible. In the three-dimensional space of the principal stresses ( $\sigma_1, \sigma_2, \sigma_3$ ), an infinite number of yield points form together a yield surface.

Knowledge of the yield point is vital when designing a component since it generally represents an upper limit to the load that can be applied. It is also important for the control of many materials production techniques such as forging, rolling, or pressing. In structural engineering, this is a soft failure mode which does not normally cause catastrophic failure or ultimate failure unless it accelerates buckling.

It is often difficult to precisely define yielding due to the wide variety of stress–strain curves exhibited by real materials. In addition, there are several possible ways to define yielding:

Figure A.1- Stress vs Strain Curve – Definitions of Yield Points

#### True elastic limit:

It is the lowest stress at which dislocations move. This definition is rarely used, since dislocations move at very low stresses, and detecting such movement is very difficult.

#### Proportionality limit:

Up to this amount of stress, stress is proportional to strain (Hooke's law), so the stress-strain graph is a straight line, and the gradient will be equal to the elastic modulus of the material.

#### Elastic limit:

Beyond the elastic limit, permanent deformation will occur. It is the lowest stress at which permanent deformation can be measured. This requires a manual load-unload procedure, and the accuracy is critically dependent on equipment and operator skill. For elastomers, such as rubber, the elastic limit is much larger than the proportionality limit. Also, precise strain measurements have shown that plastic strain begins at low stresses.

#### Offset yield point:

This is the most widely used strength measure of metals, and is found from the stress-strain curve as shown in the figure to the right. A plastic strain of 0.2% is usually used to define the offset yield stress, although other values may be used depending on the material and the application. The offset value is given as a subscript, e.g.  $R_{p0.2} = 310 \text{ MPa}$ . In some materials there is essentially no linear region and so a certain value of strain is defined instead. Although somewhat arbitrary, this method does allow for a consistent comparison of materials.

#### Upper yield point and lower yield point:

Some metals, such as mild steel, reach an upper yield point before dropping rapidly to a lower yield point. The material response is linear up until the upper yield point, but the lower yield point is used in structural engineering as a conservative value.

## A.6 Yield Criterion

A yield criterion, often expressed as yield surface, or yield locus, is an hypothesis concerning the limit of elasticity under any combination of stresses. There are two interpretations of yield criterion: one is purely mathematical in taking a statistical approach while other models attempt to provide a justification based on established physical principles. Since stress and strain are tensor qualities they can be described on the basis of three principal directions, in the case of stress these are denoted by  $\sigma_1, \sigma_2, \sigma_3$ .

The following represent the most common yield criterion as applied to an isotropic material (uniform properties in all directions). Other equations have been proposed or are used in specialist situations.

### Isotropic yield criteria:

Maximum Principal Stress Theory - Yield occurs when the largest principal stress exceeds the uniaxial tensile yield strength. Although this criterion allows for a quick and easy comparison with experimental data it is rarely suitable for design purposes.

$$\sigma_1 \leq \sigma_y \quad (8)$$

Maximum Principal Strain Theory - Yield occurs when the maximum principal strain reaches the strain corresponding to the yield point during a simple tensile test. In terms of the principal stresses this is determined by the equation:

$$\sigma_1 - \nu(\sigma_2 + \sigma_3) \leq \sigma_y \quad (9)$$

Maximum Shear Stress Theory - Known as the Tresca yield criterion, after the French scientist Henri Tresca. This assumes that yield occurs when the shear stress  $\tau$  exceeds the shear yield strength  $\tau_y$ :

$$\tau = \frac{\sigma_1 - \sigma_3}{2} \leq \tau_{ys} \quad (10)$$

Total Strain Energy Theory - This theory assumes that the stored energy associated with elastic deformation at the point of yield is independent of the specific stress tensor. Thus yield occurs when the strain energy per unit volume is greater than the strain energy at the elastic limit in simple tension.

Distortion Energy Theory - This theory proposes that the total strain energy can be separated into two components: the volumetric (hydrostatic) strain energy and the shape (distortion or shear) strain energy. It is proposed that yield occurs when the distortion component exceeds that at the yield point for a simple tensile test. This is generally referred to as the *Von Mises* yield criterion and is expressed as:

$$\frac{1}{2}[(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2] \leq \sigma_y^2 \quad (11)$$

Based on a different theoretical underpinning this expression is also referred to as octahedral shear stress theory.

Most commonly used isotropic yield criteria is the ***von Mises* yield criterion**.

#### **Von Mises yield criterion:**

The *von Mises* yield criterion suggests that the yielding of materials begins when the second deviatoric stress invariant  $J_2$  reaches a critical value  $k$ . For this reason, it is sometimes called the  $J_2$  plasticity or  $J_2$  flow theory. It is part of a plasticity theory that applies best to ductile materials, such as metals. Prior to yield, material response is assumed to be elastic.

In material science and engineering the *von Mises* yield criterion can be also formulated in terms of the *von Mises* stress or equivalent tensile stress,  $\sigma_v$ , a scalar stress value that can be computed from the stress tensor. In this case, a material is said to start yielding when its *von Mises* stress reaches a critical value known as the yield strength,  $\sigma_y$ . The *von Mises* stress is used to predict yielding of materials under any loading condition from results of simple uniaxial tensile tests. The *von Mises* stress satisfies the property that two stress states with equal distortion energy have equal *von Mises* stress.

Because the *von Mises* yield criterion is independent of the first stress invariant,  $I_1$ , it is applicable for the analysis of plastic deformation for ductile materials such as metals, as the onset of yield for these materials does not depend on the hydrostatic component of the stress tensor.

Although formulated by Maxwell in 1865, it is generally attributed to *von Mises* (1913). Huber (1904), in a paper in Polish, anticipated to some extent this criterion. This criterion is referred also as the **Maxwell–Huber–Hencky–von Mises theory**.

Mathematically the yield function for the *von Mises* condition is expressed as:

$$f(J_2) = \sqrt{J_2} - k = 0 \quad (12)$$

Where  $k$  can be shown to be the yield stress of the material in pure shear. As it will become evident later in the article, at the onset of yielding, the magnitude of the shear stress in pure shear is  $\sqrt{3}$  times lower than the tensile stress in the case of simple tension. Thus, we have:

$$k = \frac{\sigma_y}{\sqrt{3}} \quad (13)$$

Furthermore, if we define the *von Mises* stress as  $\sigma_v = \sqrt{3J_2}$ , the von Mises yield criterion can be expressed as:

$$f(J_2) = \sqrt{3J_2} - \sigma_y = \sigma_v - \sigma_y = 0 \quad (14)$$

Substituting  $J_2$  in terms of function of the stress tensor components into the von Mises criterion equation we have:

$$(\sigma_{11} - \sigma_{22})^2 + (\sigma_{22} - \sigma_{33})^2 + (\sigma_{11} - \sigma_{33})^2 + 6(\sigma_{23}^2 + \sigma_{31}^2 + \sigma_{12}^2) = 6k^2 \quad (15)$$

This equation defines the yield surface as a circular cylinder, whose yield curve, or intersection with the deviatoric plane, is a circle with radius  $\sqrt{2}k$ , or  $\sqrt{3/2}\sigma_y$ .

This implies that the yield condition is independent of hydrostatic stresses.

In the case of uniaxial stress or simple tension,  $\sigma_1 \neq 0$ ,  $\sigma_3 = \sigma_2 = 0$ , the *von Mises* criterion reduces to  $\sigma_1 = \sigma_y$ .

Therefore, the material starts to yield, when  $\sigma_1$  reaches the yield strength of the material  $\sigma_y$ , which is a characteristic material property. In practice, this parameter is, indeed, determined in a tensile test satisfying the uniaxial stress condition.

It is also convenient to define an Equivalent tensile stress or *von Mises* stress,  $\sigma_v$ , which is used to predict yielding of materials under multiaxial loading conditions using results from simple uniaxial tensile tests. Thus, we define

$$\sigma_v = \sqrt{3J_2} = \sqrt{\frac{3}{2}s_{ij}s_{ij}} \quad (16)$$

Where  $s_{ij}$  are the components of the stress deviator tensor  $\sigma^{dev}$ :

$$\sigma^{dev} = \sigma - \frac{1}{3}(\sigma \cdot I)I \quad (17)$$

**Von Mises criterion for different stress conditions:**

In this case, yielding occurs when the equivalent stress,  $\sigma_v$ , reaches the yield strength of the material in simple tension,  $\sigma_y$ .

As an example, the stress state of a steel beam in compression differs from the stress state of a steel axle under torsion, even if both specimens are of the same material. In view of the stress tensor, which fully describes the stress state, this difference manifests in six degrees of freedom, because the stress tensor has six independent components. Therefore, it is difficult to tell which of the two specimens is closer to the yield point or has even reached it. However, by means of the *von Mises* yield criterion, which depends solely on the value of the scalar *von Mises* stress, i.e., one degree of freedom, this comparison is straightforward: A larger *von Mises* value implies that the material is closer to the yield point.

In the case of pure shear stress,  $\sigma_{12} = \sigma_{21} \neq 0$ , while all other  $\sigma_{ij} = 0$ , *von Mises* criterion becomes:

$$\sigma_{12} = k = \frac{\sigma_y}{\sqrt{3}} \quad (18)$$

This means that, at the onset of yielding, the magnitude of the shear stress in pure shear is  $\sqrt{3}$  times lower than the tensile stress in the case of simple tension. The *von Mises* yield criterion for pure shear stress, expressed in principal stresses, is:

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_1 - \sigma_3)^2 = 6\sigma_{12}^2 \quad (19)$$

In the case of plane stress,  $\sigma_3 = 0$ , the *von Mises* criterion becomes:

$$\sigma_1^2 - \sigma_1\sigma_2 + \sigma_2^2 = 3k^2 = \sigma_y^2 \quad (20)$$

This equation represents an ellipse in the plane  $\sigma_1 - \sigma_2$ .

**Mohr-Coulomb yield criterion:**

Mohr-Coulomb theory is a mathematical model describing the response of a material such as rubble piles or concrete to shear stress as well as normal stress. Most of the classical engineering materials somehow follow this rule in at least a portion of their shear failure envelope.

In structural engineering it is used to determine failure load as well as the angle of fracture of a displacement fracture in concrete and similar materials. Coulomb's friction hypothesis is used to determine the combination of shear and normal stress that will cause a fracture of the material. Mohr's circle is used to determine which principal stresses that will produce this combination of shear and normal stress, and the angle of the plane in which this will occur. According to the principle of normality the stress introduced at failure will be perpendicular to the line describing the fracture condition.

It can be shown that a material failing according to Coulomb's friction hypothesis will show the displacement introduced at failure forming an angle to the line of fracture equal to the angle of friction. This makes the strength of the material determinable by comparing the external mechanical work introduced by the displacement and the external load with the internal mechanical work introduced by the strain and stress at the line of failure. By conservation of energy the sum of these must be zero and this will make it possible to calculate the failure load of the construction.

A common improvement of this model is to combine Coulomb's friction hypothesis with Rankine's principal stress hypothesis to describe a separation fracture.

The Mohr-Coulomb yield surface is often used to model the plastic flow of geomaterials (and other cohesive-frictional materials). Many such materials show dilatational behaviour under triaxial states of stress, which the Mohr-Coulomb model does not include. Also, since the yield surface has corners, it may be inconvenient to use the original Mohr-Coulomb model to determine the direction of plastic flow (in the flow theory of plasticity).

A common approach that is used is to use a non-associated plastic flow potential that is smooth. An example of such a potential is the function

$$g = \sqrt{(\alpha c_y \tan \psi)^2 + G^2(\phi, \theta) q^2} - p \tan \phi \quad (21)$$

where  $\alpha$  is a parameter,  $c_y$  is the value of  $c$  when the plastic strain is zero (also called the initial cohesion yield stress),  $\psi$  is the angle made by the yield surface in the Rendulic plane at high values of  $p$  (this angle is also called the dilation angle), and  $G(\phi, \theta)$  is an appropriate function that is also smooth in the deviatoric stress plane.

### **Drucker-Prager yield criterion**

The Drucker-Prager yield criterion is a pressure-dependent model for determining whether a material has failed or undergone plastic yielding. The criterion was introduced to deal with the plastic deformation of soils. It and its many variants have been applied to rock, concrete, polymers, foams, and other pressure-dependent materials.

The Drucker-Prager yield criterion has the form

$$\sqrt{J_2} = A + B I_1 \quad (22)$$

where  $I_1$  is the first invariant of the Cauchy stress and  $J_2$  is the second invariant of the deviatoric part of the Cauchy stress. The constants A, B are determined from experiments.

In terms of the equivalent stress (or *Von Mises* stress) and the hydrostatic (or mean) stress, the Drucker-Prager criterion can be expressed as

$$\sigma_e = a + b \sigma_m \quad (23)$$

Where  $\sigma_e$  is the equivalent stress,  $\sigma_m$  is the hydrostatic stress, and a, b are material constants.

The Drucker-Prager yield surface is a smooth version of the Mohr-Coulomb yield surface.

#### **Bresler-Pister yield criterion:**

The Bresler-Pister yield criterion is a function that was originally devised to predict the strength of concrete under multiaxial stress states. This yield criterion is an extension of the Drucker-Prager yield criterion and can be expressed on terms of the stress invariants as

$$\sqrt{J_2} = A + B I_1 + C I_1^2 \quad (24)$$

where  $I_1$  is the first invariant of the Cauchy stress,  $J_2$  is the second invariant of the deviatoric part of the Cauchy stress, and A, B, C are material constants.

Yield criteria of this form have also been used for polypropylene and polymeric foams.

The parameters A,B,C have to be chosen with care for reasonably shaped yield surfaces.

## **Appendix B      DEFORMATION      MECHANISMS      AND      EXISTING APPROACHES TO FATIGUE LIFE PREDICTION (outline)**

### **B.1 Deformation mechanisms**

Deformation models play a significant role into material description abilities.

The active deformation mechanism in a material depends on the homologous temperature, confining pressure, strain rate, stress, grain size, presence or absence of a pore fluid, presence or absence of impurities in the material. Note these variables are not fully independent e.g. for a pure material of a fixed grain size, at a given pressure, temperature and stress, the strain-rate is given by the flow-law associated with the particular mechanisms. More than one mechanism may be active under a given set of conditions and some mechanisms cannot operate independently but must act in conjunction with another in order that significant permanent strain can develop. In a single deformation episode, the dominant mechanism may change with time e.g. recrystallization to a fine grain size at an early stage may allow diffusive mass transfer processes to become dominant.

The recognition of the active mechanisms in a material almost always requires the use of microscopic techniques, in most cases using a combination of optical microscopy, SEM and TEM.

Using a combination of experimental deformation to find the flow-laws under particular conditions and from microscopic examination of the samples afterwards it has been possible to represent the conditions under which individual deformation mechanisms dominate for some materials in the form of deformation mechanism maps.

Five main mechanisms are recognized; cataclasis, dislocation creep, recrystallization, diffusive mass transfer and grain-boundary sliding.

Cataclasis is a mechanism that operates under low to moderate homologous temperature, low confining pressure and relatively high strain rates.

Dislocation creep is the main process but cannot act on its own to produce large strains due to the effects of strain hardening. Some form of recovery process, such as dislocation climb or grain-boundary migration must also be active.

Dynamic recrystallization: two main mechanisms of recrystallization are known, sub-grain rotation and grain boundary migration, and only the former involves actual deformation. Grain boundary migration involves no strain in itself, but is one of the recovery mechanisms that can allow dislocation processes to proceed to large strains.

Diffusive mass transfer: in this group of mechanisms, strain is accommodated by a change in shape involving the transfer of mass by diffusion; through the lattice (Nabarro-Herring creep), the grain boundaries (Coble creep) and via a pore fluid (Pressure solution).

- Nabarro-Herring creep acts at high homologous temperatures and is grain size dependent with the strain-rate inversely proportional to the square of the grain size.

- Coble-creep acts at high homologous temperatures and is strongly grain-size dependent, with a flow-law where strain-rate is inversely proportional to the cube of the grain size .
- Pressure solution operates at moderate homologous temperatures and relatively low strain-rates and requires the presence of a pore fluid.

Grain-boundary sliding: this mechanism must act with another to change the shapes of the grains so that they can slide past each other without creating significant voids. This mechanism, acting with diffusive mass transfer has been linked with the development of super-plasticity.

## B.2 Existing approaches to the prediction of fatigue life

Fatigue is defined as a process of the cycle-by-cycle accumulation of damage in a material undergoing fluctuating stresses and strains. A significant feature of fatigue is that the load is not large enough to cause immediate failure. Instead, failure occurs after a certain number of load fluctuations have been experienced, i.e., after the accumulated damage has reached a critical level. Fatigue of metals and metal structures has been studied for more than 160 years and a good understanding of metal fatigue mechanisms has been achieved. Fatigue cracks usually start from the surface of a component, where fatigue damage begins as shear cracks on crystallographic slip planes. The surface shows the slip planes as intrusions and extrusions. This is stage I crack growth. After a transient period, stage II crack growth takes place in a direction normal to the applied stress.

Finally, the crack becomes unstable and fracture occurs.

Figure B.1- Schematic representation of crack formation and growth in polycrystalline metals

A mechanical part is exposed to a complex, often random, sequence of loads, large and small. In order to assess the safe life of such a part is necessary to reduce the complex loading to a series of simple cyclic loadings using a technique such as Rainflow analysis. For this type of technique is necessary to create a histogram of cyclic stress vs time. For each stress level, is necessary to calculate the degree of cumulative damage incurred from the S-N curve; and combine the individual contributions using an algorithm such as Miner's rule.

### Miner's rule:

In 1945, M. A. Miner popularised a rule that had first been proposed by A. Palmgren in 1924. The rule, variously called Miner's rule or the Palmgren-Miner linear damage hypothesis, states that where there are  $k$  different stress magnitudes in a spectrum,  $S_i$  ( $1 \leq i \leq k$ ), each contributing  $n_i(S_i)$  cycles, then if  $N_i(S_i)$  is the number of cycles to failure of a constant stress reversal  $S_i$ , failure occurs when:

$$\sum_{i=1}^k \frac{n_i}{N_i} = C \quad (1)$$

$C$  is experimentally found to be between 0.7 and 2.2. Usually for design purposes,  $C$  is assumed to be 1. This can be thought of as assessing what proportion of life is consumed by stress reversal at each magnitude then forming a linear combination of their aggregate.

Though Miner's rule is a useful approximation in many circumstances, it has two major limitations: It fails to recognise the probabilistic nature of fatigue and there is no simple way to relate life predicted by the rule with the characteristics of a probability distribution.

There is sometimes an effect in the order in which the reversals occur. In some circumstances, cycles of low stress followed by high stress cause more damage than would be predicted by the rule. It does not consider the effect of overload or high stress, which may result in a compressive residual stress. High stress followed by low stress may have less damage due to the presence of compressive residual stress.

#### **Paris's relationship:**

Anderson, Gomez and Paris derived relationships for the stage II crack growth with cycles  $N$ , in terms of the cyclical component  $\Delta K$  of the Stress Intensity Factor  $K$ :

$$\frac{da}{dN} = C(\Delta K)^m \quad (2)$$

where  $a$  is the crack length and  $m$  is typically in the range 3 to 5 (for metals).

This relationship was later modified (by Forman, 1967) to make better allowance for the mean stress, by introducing a factor depending on  $(1-R)$  where  $R = \text{min. stress}/\text{max stress}$ , in the denominator.

#### **Low cycle fatigue. Coffin-Manson relation:**

Where the stress is high enough for plastic deformation to occur, the account in terms of stress is less useful and the strain in the material offers a simpler description. Low-cycle fatigue is usually characterised by the Coffin-Manson relation (published independently by L. F. Coffin in 1954 and S. S. Manson 1953):

$$\frac{\Delta \epsilon_p}{2} = \epsilon'_f (2N)^c \quad (3)$$

Where:

- $\Delta\epsilon_p/2$  is the plastic strain amplitude
- $\epsilon_f'$  is an empirical constant known as the fatigue ductility coefficient, the failure strain for a single reversal
- $2N$  is the number of reversals to failure ( $N$  cycles)
- $c$  is an empirical constant known as the fatigue ductility exponent, commonly ranging from -0.5 to -0.7 for metals.

## Appendix C      User-defined models implementation in FEM software - Theories

In this section it will be provided an overview of the main theories for the implementation of user-defined material models in FEM software.

### C.1 Stress-rate based theories

As macroscopic plasticity theories are usually based on a yield condition, we have to identify this feature within the microscopic theory. The need of consistent physically based definitions for the yield surface is here required for dynamic localizations.

In inelastic deformation, the localization of deformation into narrow bands of intense straining is considered one of the characteristic features in metals and steel alloys. Localization for the case of rate-independent formulation is associated with a change in the character of the governing equations. That is, under quasi-static loading conditions the equations governing incremental equilibrium lose ellipticity, while under dynamic loading conditions wave speeds become imaginary.

Standard boundary value problems are then ill posed; one manifestation of this is that the width of the band of localized deformation is arbitrary narrow. As a consequence numerical solutions to localization problems for rate-independent solids exhibit inherent mesh dependence. The minimum width of the band of localized deformation is set by the mesh spacing. Furthermore, global quantities such as the overall stiffness characteristics of the body depend on the mesh size used to resolve the band of localized deformations.

Under both quasi static and dynamic loading conditions, the solutions to localization problems for rate-independent solids permit arbitrary narrow bands of intense deformation. There is nothing in the formulation to set a minimum width to such bands. On the other hand, in numerical solutions the minimum width is set by the mesh spacing and key features of the solutions can be a consequence of the discretization. This is clearly an undesirable state of affairs and stems from the character of the continuum problem.

#### **Stress evolution representative functional:**

The development of stress integration algorithms with improved performance has received considerable attention in the recent literature on computational plasticity and visco-plasticity.

The very efficient implementations of the implicit integration using the radial return schemes for metals corresponding to the special case of full isotropy (both elastic and inelastic responses), enabled by the complete reductions of the rate tensor equations to a final single/scalar nonlinear equation; e.g. in terms of the effective stress, or equivalently the plastic multiplier or the “magnitude” of the inelastic strain vector. In order to achieve a strong algorithmic treatment for any complex visco-plasticity constitutive models used for large-scale deformation, the following three tasks are required (Saleeb et al., 2000); (1) detailed study of the mathematical structure of the Visco-plastic equations, and the corresponding integrated field of stress and internal state variables, (2) development and

implementation of the implicit backward-Euler stress-updating algorithm, and the associated nonlinear iteration equation solver (e.g. Newton Raphson technique), (3) testing the convergence, stability, and accuracy properties of the algorithms.

On the theoretical side, the general framework is developed in the specific context of the fully implicit (backward Euler) difference scheme which is known to exhibit excellent convergence and accuracy characteristics in large scale computations that involve large time steps, particularly with complex anisotropic inelastic models (Ortiz and Popov, 1985). Radial return algorithm which is a special case of the backward-Euler method is used to introduce a nonlinear scalar equation in terms of the Visco-plastic multiplier for the case of the Consistency Visco-plastic model and in terms of the equivalent stress for the case of Perzyna Visco-plastic model. Consistent algorithmic tangent stiffness matrices are derived for both small and finite strain Visco-plastic models.

### **Plasticity constitutive equations:**

Nemat-Nasser and his co-workers (1991, 1992) developed an experimental technique measuring the flow stress of different bcc, fcc and hcp metals and alloys over a broad range of strains, strain rate, and temperatures in uniaxial compression.

Some of their experimental results are, actually, used in this work for models evaluation and comparisons. They also presented a constitutive model that characterizes the plastic deformation of different metals and alloys using the thermal activation concept and assuming constant dislocation density throughout the deformation process. That is neither the plastic strain evolution of dislocation density nor the rate multiplication of the dislocation density evolution is considered.

There has been a significant progress made over the years in the development theories of plasticity and visco-plasticity for the phenomenological representation of inelastic constitutive properties. In particular, mathematical modelling of metal visco-plasticity developed based on the so-called internal state variable formalism in the thermodynamics of irreversible processes.

A large number of specialized forms of these modern unified Visco-plastic models (e.g. isotropic or anisotropic, fully associative or non-associative, isothermal or non-isothermal, etc.) have been successfully applied to different metals with different crystal structures (Coleman and Gurtin, 1967; Lubliner, 1973; Germain et al., 1983; Lemaitre and Chaboche, 1990; Arnold and Saleeb, 1994; Robinson and Duffy, 1990; Arnold et al., 1995; Robinson et al., 1987; Freed and Walker, 1993; Simo and Taylor, 1985).

### **Equilibrium surface evolution:**

Zerilli and Armstrong (1987) used equilibrium equations to describe the dislocation mechanics concept to develop a constitutive model that accounts for strain, strain rate and temperature dependence in a coupled manner, which can be incorporated in high rates of loading related computer codes. Their model considers two different forms for the two different classes of metals; body centred cubic (bcc) and face centred cubic (fcc). The rationale for the differences in the two forms mainly depends on the dislocation characteristics for each this particular structure. Bcc metals show stronger dependence of the yield stress on temperature and strain rate while in the case of (fcc) metals the yield

stress is mainly affected by strain hardening. In other words, the cutting of dislocation forests is the principal mechanism in (fcc) metals, while in bcc metals; the overcoming of Peierls-Nabarro barriers is the principal mechanism.

These two different dislocation mechanisms of the two different metal classes will be further investigated in the following sections. The Zerilli-Armstrong model has been derived based on the concept of thermal activation analysis for overcoming local obstacles to dislocation motion. This model has been widely used in many computer codes from which its material parameters are physically interpreted. In fact, this physical interpretation of material constants becomes meaningless if one tries to identify them from the experimental data by using a very small reference strain rate rather than using the one corresponding to the reference dislocation velocity as been derived in the their model. Moreover, their material parameters lose their physical meaning when they are used for high temperature and strain rate applications which will be discussed in the following sections. It has been shown that the Zerilli-Armstrong model as compared to the Johnson-Cook model gives slightly better correlation with experimental results; however, none of these two models is very accurate in describing the behaviour of metals at very large strains (Johnson and Holmquist, 1988).

## **C.2 Strain-rate based theories**

In dynamic problems that introduce high strain rates, the dynamic yield stress is considered the most important expression needed to characterize the material behaviour and is also used in finite element codes. Although we are concerned with the macroscopic response of the plastic flow, investigating the grain and atomic level of the material deformation will help us understand the failure mechanisms for different material structures.

Accordingly, the definition of dynamic yield (flow) stress differs from metal to metal depending on their internal crystal structure; body centred cubic (bcc), face centred cubic (fcc), hexagonal close packing (hcp), and others. These crystal structure differences affect differently the dislocations movement during the plastic deformation process under high strain rates loading. Each of these three crystal structures exhibits a characteristic thermo mechanical behaviour which is associated with the available slip systems and symmetries as well as the nature of dislocation cores. The visco-plastic deformation of steel alloys is generally controlled by the dislocation mechanisms attributed to the content of their compositions. The percentage of carbon in steel plays a crucial role in determining the phase behaviour (Ferrite and Austenite) of the material over a wide range of temperatures.

Generally, the plastic flow is characterized macroscopically as a visible distortion, microscopically as the appearance of slip systems, and atomically as a movement of dislocations. Microscopic plasticity in metals is primarily the result of dislocation moving through the crystal lattice. The interaction of these dislocations with the lattice and the various obstacles encountered through the lattice determine the flow strength of the material. The motion of a dislocation through the lattice or past an obstacle requires the surmounting of an energy barrier by a combination of applied stress and thermal activation.

The result is that the effective shear stress required to generate an overall plastic strain rate is intimately tied to the temperature at which the deformation occurs. Competing thermal activation effects will influence deformations that occur at both high temperature and high strain rates. The

coupling of rate and temperature through dislocation kinematics indicates that the rate of thermal softening of metals should be related to the rate of deformation. These considerations are particularly important in the development of material models for use within simulation of high-rate phenomena, which generally involve high temperatures because of adiabatic heating.

#### **Residual strain evolution functions:**

The modelling the dynamic flow stress of the material plastic flow at high strain rates and elevated temperatures was the main aim of the research programmes. Studies were made in characterizing material behaviour through both phenomenological and physically based models. Empirical equations were initially developed with simple uniaxial stress-strain models and one-dimensional stress wave propagation models by describing the effect of temperature and strain hardening as well as strain rate on the flow stress.

However, for the *von Mises* type material, the one-dimensional models that express flow stress as a function of strain and strain rate can be converted into the equivalent three-dimensional material models by replacing stresses, strains, and strain rates by their equivalent invariant three-dimensional forms.

Johnson and Cock (1983) proposed a phenomenological model that is widely used in most computer codes for static and dynamic analyses in order to predict the behaviour of the material flow stress at different strain rates ( $10^{-4}\text{s}^{-1}$ - $10^{-5}\text{s}^{-1}$ ) and temperatures. The main advantage of this model is that it is relatively easy to calibrate with a minimum of experimental data in the form of stress-strain curves at different strain rates and temperatures.

Moreover, the strain rate and temperature effects on the flow stress are uncoupled which implies that the strain rate sensitivity is independent of temperature. This is not the case as observed in most metals. It is rather found that the rate sensitivity increases with increasing temperature while the flow stress decreases. For this reason was born a new branch of theories able to keep into account of these effects (Hoge and Murkherjee, 1977)

#### **Strain potentials based methods:**

The understanding of high-strain-rate behaviour of metals is essential for the modelling and analysis of numerous processes including high-speed machining, impact, penetration and shear localization. Recently, considerable progress has been made in understanding the role of rate controlling dislocation mechanisms on the temperature and strain rate dependence of the flow stress for metals and alloys. Hoge and Murkherjee (1977) studied the effect of both temperature and strain rates on the lower yield stress of Tantalum and proposed a model incorporating the combined operation of the Peierls' mechanism and dislocation drag process.

They concluded from the stress-temperature relationship and the variation of the activation volume with stress and strain that the rate controlling mechanism for deformation could be rationalized in terms of Peierls mechanism. This behaviour is mainly attributed to the specific crystal structure of body cubic centred metals. Steinberg and co-workers (see for example, Steinberg and Lund, 1989) described a constitutive model for use with hydrodynamic codes to account for the dependence of

shear modulus and yield strength on high strain rates, temperature, and pressure-dependent melting. Although their model is intended to be used at high strain rates, their formulation did not specifically include strain rate effects.

This model has been widely used in many computer codes from which its material parameters are physically interpreted. In fact, this physical interpretation of material constants becomes meaningless if one tries to identify them from the experimental data by using a very small reference strain rate rather than using the one corresponding to the reference dislocation velocity as been derived in the model. It has been shown that the Zerilli-Armstrong model as compared to the Johnson-Cook model gives slightly better correlation with experimental results; however, none of these two models is very accurate in describing the behaviour of metals at elevated temperatures (Johnson and Holmquist, 1988; Abed and Voyiadjis, 2005).
